The accuracy of the NIR opens up a totally new argument. One side of the argument says that the NIR cannot be more accurate than the standard, whereas the other side says that if we have enough samples in our calibration set the random errors of the standard method will be averaged out and therefore the NIR is more accurate (closer to the truth) than the standard model. Unfortunately, while I side with the second argument,

On-line customer results can typically be more accurate than the general results reported here when calibration models are developed for the customer’s specific type of fuel. Calibration model results will depend on the laboratory analysis of the samples using the primary method. Note that the ASTM (American Standard Testing Method) SEP (standard error of prediction, measured on samples not in modeling set) is defined as the reproducibility reported in the method divided by 2.77 and that the PIONIR (Orbital’s third overtone NIR instrument) repeatability data are based on 120 repeated scans of a static sample over 48 hours.

*Not applicable.*

*Not measured.*
the “jury is out” on this entire issue. The problem is that even if the NIR is more accurate on a given sample than the standard method, there is no way to prove it with one laboratory test.

5 DIESEL

Another major product of most refineries is diesel fuel. Although there are no literature references to the NIR applications for diesel, the system can be used to determine:

1. Cetane number
2. Cetane index
3. Aromatic concentration
4. Saturate concentration
5. Viscosity
6. Specific gravity
7. T10 (temperature at which 10% of the fuel has been distilled off)
8. T50
9. T90
10. R250 (amount distilled off at 250°C – note the use of °C vs. °F in T-numbers)
11. R350
12. Flash point (temperature in °C at which fuel supports a flame)
13. Cloud point (temperature at which fuel becomes cloudy, in °C)
14. Pour point (temperature at which fuel will not pour, in °C).

The cetane numbers are measures of fuel quality for a diesel engine like octane numbers are for the gasoline engine. Because of the extreme difference in ignition methods of the two engines, the cetane numbers and cetane numbers are almost anti-correlated – straight chain molecules have a low octane number and high cetane number.

The cetane index measures how the fuel will respond to certain additives, cetane improvers – vital information so the refiner can put in the correct amount of additive. The cloud point and pour point are important values but difficult to obtain in the laboratory because of the time and operator attention required to get repeatable results.

The results using one type of NIR instrument available from Orbital Sciences are shown in Table 1.

6 CONCLUSION

What the above has shown is that the NIR spectrum contains valuable information to optimize the refinery operation. One large refinery gave the NIR credit for adding 40 million dollars to the “bottom line” in the first year of operation. This saving resulted from fast, precise, and, this refinery believed, accurate results of the NIR.

Nuclear magnetic resonance (NMR) spectroscopy is a powerful analytical method for determining the structure of an organic material. Developments in NMR have allowed high-resolution spectra of materials in the solid state to be obtained. Thus, materials that have been intractable, such as kerogens and sedimentary organic matter, can now be characterized for their organic carbon structure. The combination of solid- and liquid-state NMR makes NMR one of the most useful methods for the characterization of petroleum and its products.

Petroleum is formed from the maturation of sedimentary organic matter as a result of burial over geological timescales. Everyone is familiar with the products of petroleum, i.e. gasoline, diesel fuels, chemicals, and so on. All these materials, including the petroleum source rock material, can now be studied by NMR, from the genesis of petroleum to finished products such as transportation fuels. In this article, some applications of solid- and liquid-state NMR to the characterization of petroleum source rocks and petroleum end products are described.

1 INTRODUCTION

1.1 Scope

In an encyclopedia article such as this, which deals with NMR studies of petroleum and related materials, it is not practical to cite and discuss all the applications of NMR to the analysis of petroleum. This would require a great deal more space and the article would be more of a textbook or review-type article than an encyclopedic article. Consequently, the applications are necessarily limited, as are the citations for a given topic. It is hoped to provide sufficient information here for the reader to obtain an appreciation of the uses of NMR in petroleum analyses, or to give sufficient citations to direct the reader to more detailed information about a particular application.

The applications range from the maturation of petroleum source rocks to the end-use of petroleum as distillate products, and include solid- and liquid-state NMR applications. For a more detailed discussion of NMR techniques, the reader is referred to the Related Articles section at the end of this article for additional reading on Solid-state Nuclear Magnetic Resonance and liquid-state NMR (Carbon-13 Nuclear Magnetic Resonance Spectroscopy). Only a rudimentary discussion is included here. The objectives are to introduce the analytical application of NMR to the researcher who wishes to acquire an understanding of some of the methods and terminology that are most often encountered in the literature.
1.2 Historical Development

The possible applications of NMR to the characterization of petroleum and petroleum products were first discussed in 1955 and the first reports of the use of $^1$H NMR were published in 1957 as discussed in Retcofsky et al.\(^1\)

Quantitation of the elemental hydrogen content of petroleum materials using $^1$H NMR was reported in 1959\(^2\) and the first quantitative $^{13}$C NMR spectrum of a petroleum fraction by a time-averaged slow passage technique was reported in 1967.\(^3\) It was not until 1976, shortly after the development of Fourier transform NMR, that quantitative $^{13}$C investigation of crude oils and petroleum products started to become routine.\(^4\)

The development of solid-state NMR techniques of cross-polarization (CP) and magic angle spinning (MAS) with high-power decoupling in the mid 1970s provided a great advance in characterizing and understanding the chemical nature of the organic matter in sedimentary rocks. These techniques provide information about the carbon structure of the organic matter in the rock without the need for preparation of kerogen concentrates. Some of the first published CP and CP/MAS $^{13}$C NMR spectra were of coals\(^5,6\) and oil shales\(^7,8\) materials that are largely insoluble and for which few good techniques then existed for probing the carbon structure of these fossil fuels.

2 SOLID-STATE NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM SOURCE ROCKS

2.1 Experimental Procedures and Instrumentation

Sample preparation in solids NMR is relatively straightforward. The sample must be ground to a sufficiently small particle size, so that the NMR spinners can be packed uniformly in order to spin the samples at high speeds without difficulty. A 100-mesh sample size is ideal because this particle size is acceptable for elemental analyses (C, H, O, N, S) as well. Larger particle sizes can be used. The criteria are that the spinner can be balanced easily and that the sample placed in the spinner is representative of the material under investigation. The sample should be free of magnetic materials. In situations where there is not enough sample material to fill a spinner, or the particle size leads to an unbalanced spinner, other materials such as sulfur, or salt (NaCl) can be added to provide ballast to the spinner. Salt works well because the sample material can be recovered easily by washing. This is especially useful for kerogen samples, which are usually prepared in small quantities.

A field of 2.3 Tesla (100 MHz for $^1$H, 25 MHz for $^{13}$C) is about optimum for solid-state NMR measurements on solid fossil-fuel materials including source rocks. At this field strength, spinning rates up to 5 kHz can easily be obtained for spinners of 7.5-mm diameter. In addition, large-volume spinners with diameters of about 14 mm can also be spun at rates of about 4 kHz.\(^9\) These rates are sufficient to minimize interferences caused by spinning sidebands associated with the chemical shift anisotropy. The increased sample size of a large-volume spinner has the advantage of increasing the signal-to-noise ratio (S/N), all other parameters being equal. For example, a typical 7.5-mm sample spinner has a volume of ca. 0.5 mL. A large-volume spinner has a volume of ca. 2.25 mL. Obviously, the greater the sample size, the shorter the time required to obtain a spectrum with a given S/N.

A variety of compounds have been mixed with oil shale and coals as internal standards to determine the percentage of carbons observed in CP and single-pulse NMR measurements.\(^10–14\) In some cases, the spinner material, Delrin® has been used as an internal standard.\(^9\) An excellent reference material is tetraakis(trimethylsilyl) silane (TKS).\(^11,12\) Furthermore, treatment with samarium(II) iodide has been shown to selectively reduce the free radical content, which in turn leads to an increase in the percentage of observable carbon.\(^12\) For example, treatment of Wyodak sub-bituminous coal with samarium(II) iodide increased the percentage of observable carbons by 27%, leading to an increase in the carbon aromaticity of ca. 10% from 0.66 to 0.73. This technique should work on petroleum source rock samples, although it has yet to be tried on these types of sample.

The issue of quantitation in CP has been recognized since the beginning of its application to fossil fuels.\(^15–21\) The main concerns are whether all carbons are observed equally in the CP experiment, and whether the fraction of carbons observed are a faithful enough representation so that the small loss of signal from carbons that are not observed can be ignored. Other concerns relate to such things as sample heterogeneity, spinning sidebands, unpaired electrons, MAS, and the pulse repetition rate. The problems associated with quantitation of $^{13}$C NMR measurements in carbonaceous solids have been reviewed.\(^21\)

2.2 Nuclear Magnetic Resonance Measurements of Solids

2.2.1 Cross-polarization with Magic Angle Spinning

CP NMR relies on the presence of an abundant spin system ($^1$H) to enhance the observation of a signal from a dilute spin system ($^{13}$C). The idea is to transfer polarization (and hence signal intensity) from the abundant $^1$H spins to the dilute $^{13}$C spins.\(^22\) CP is a technique that enhances the sensitivity by a factor of four over the conventional single-pulse method. The
CP experiment consists of four basic timed sequences of radiofrequency (RF) pulses. The four-part procedure consists of (1) polarization of the $^1$H spin system, (2) spin-locking in the rotating frame, (3) establishment of $^{13}$C→$^1$H contact, and (4) observation of the $^{13}$C free-induction decay (FID). CP/MAS NMR is discussed in greater detail in Solid-state Nuclear Magnetic Resonance in this encyclopedia.

2.2.2 Dipolar Dephasing

The technique of dipolar dephasing (DD) is a variation of CP. In this case, the $^1$H decoupler is switched off for a short time after the CP contact time. During this off-time, signals from different carbon types dephase at different rates, depending on the strength of the $^1$H→$^{13}$C dipolar interactions. The characteristic time for this dephasing is $T_2$, the spin–spin relaxation time. Carbons that are directly attached to hydrogen (primary, secondary, and tertiary carbons) experience strong $^1$H→$^{13}$C interactions and dephase more rapidly (∼20 µs) than carbons without attached hydrogen (quaternary carbons) (50–100 µs). After about 50 µs the decoupler is switched on again and the observed signal is due primarily to quaternary carbons. However, because of their rapid rotation in the solid state, the signals from methyl groups (CH$_3$) do not completely dephase and are observed as part of the aliphatic carbon signal. These methyl carbons can be distinguished from the other quaternary aliphatic carbons on the basis of chemical shifts. Thus DD is a technique that discriminates between protonated and nonprotonated aliphatic and aromatic carbons. This information can be useful in deriving average molecular structures for insoluble solid materials such as kerogen and asphaltenes.

2.2.3 Single-pulse Excitation

The most fundamental and most quantitative NMR measurement is made using single-pulse excitation (SPE), sometimes referred to as Bloch decay. For $^{13}$C NMR measurements in solids, SPE measurements are made in conjunction with high-power decoupling to minimize broadening caused by the $^1$H→$^{13}$C dipole–dipole interaction and with MAS to eliminate broadening caused by the chemical shift anisotropy. SPE can be employed as an independent check of the quantitative reliability of CP/MAS aromaticity measurements.$^{123,24}$ The signals from SPE arise from relaxation mechanisms that are different from those in the CP experiment. Therefore, agreement between carbon aromaticities from the two measurements indicates that both measurements are observing the same types and amounts of carbon. However, in solids, $^{13}$C spin lattice relaxation times can be on the order of minutes, necessitating long acquisition times to record an NMR spectrum. For example, a typical SPE/DD experiment employing 10 delays, 1000 scans, and a 20-s pulse delay takes 56 h.$^{24}$ Thus, the advantage of having quantitative data is partially offset by longer signal accumulation times to obtain a spectrum with a reasonably good S/N. The use of a large-volume sample spinner can negate much of this disadvantage because less time is required to obtain a good S/N.$^{9}$ Although NMR spectroscopists realize that there has been an improvement in quantitation

![Figure 1](image.png)

Figure 1 CP/MAS $^{13}$C NMR spectrum of sub-bituminous coals, illustrating resolution typical of solid-state NMR.
using SPE methods, CP/MAS still is used more frequently because of the considerable saving in time.

### 2.3 Applications

#### 2.3.1 Typical Nuclear Magnetic Resonance Spectrum of Carbonaceous Solid

A CP/MAS $^{13}$C NMR spectrum of a carbonaceous solid is shown in Figure 1. The spectrum is that of a sub-bituminous coal. It illustrates the resolution typically obtained by CP/MAS NMR for these types of material, provided they have a sufficiently high percentage of total organic carbon (TOC) to give a good S/N in a reasonable amount of time (e.g. 1 h). The positions of different carbon types are shown on the spectrum. A listing of chemical shifts for the most common carbon functional groups is given in Table 1.\(^{(25)}\) There is little resolution in the aliphatic carbon region (0–60 ppm), except for shoulders on the methylene band caused by methyl groups on aromatic rings and terminal methyl groups on long-chain paraffins. The aromatic carbon region shows more resolution from alkyl substituents, phenolic carbons, and carbonyl functionality. The main structural parameter obtained by CP/MAS is a measurement of the carbon aromaticity, i.e. the fraction of total carbon that is in aromatic (sp$^2$) carbon structures. Contributions from carbonyl carbons are often included in aromaticity measurements if the integrated signal intensity for the carbonyl carbons (165–210 ppm) is small. The spectrum was obtained at a spinning rate of 4.5 kHz, so spinning sidebands at 300 and $\pm$50 ppm are negligible. A petroleum source rock having a low TOC (<5%) would give a noisier signal and the shoulders, although present on the aliphatic and aromatic bands, would be more difficult to observe.

#### 2.3.2 Natural Maturation with Depth of Burial

Thermal evolution of source rocks during natural maturation as a result of burial, or during artificial maturation as in pyrolysis, changes many of the physical and chemical properties of the organic matter (kerogen) in sedimentary rocks.\(^{(26,27)}\) A depiction of thermal degradation of a hypothetical kerogen molecule is shown in Figure 2. In this example, temperature increases from top to bottom. The example shows the types of chemical change that are expected to occur during hydrocarbon generation resulting from burial for periods of geological time, or from elevated temperatures over short periods of time in the laboratory. In either situation, the thermal alteration of kerogen involves hydrogen disproportionation reactions in which the kerogen loses hydrogen to form liquid hydrocarbons, wet gas and dry gas in succession. The remaining hydrogen-deficient kerogen condenses to form larger aromatic clusters which would eventually form graphite.

The main chemical change depicted in Figure 2 is the progressive decrease in H/C (atomic hydrogen to carbon) ratio (increase in the carbon aromaticity) of the kerogen with increasing maturation. This change is brought about by aromatization of aliphatic carbons in hydroaromatic structures (tetralin type) and by cyclization and dehydrogenation of alkyl substituents. In addition, the number of

side chains on the aromatic ring system decreases with maturation. The products of the reactions progressively become lower in molecular weight, with methane, CH₄, being the ultimate product. For simplicity, only hydrocarbon structures are shown; however, similar changes would be expected to occur with heteroatoms (N, S, O) in the ring system.

2.3.3 Changes in Nuclear Magnetic Resonance Spectra with Depth of Burial

NMR measurements provide important information on the catagenesis and maturation of the organic matter in sedimentary rocks. The chemical changes depicted in Figure 2 are observed as changes in the NMR spectra of sedimentary organic matter as a function of burial depth or temperature. Most NMR measurements show how the distribution of aliphatic and aromatic carbon changes with time and temperature during burial. CP/MAS ¹³C NMR spectra for a suite of samples from the Wind River Basin in Wyoming representing different depths of burial are shown in Figure 3. The NMR spectra exhibit features that clearly support the types of chemical reaction in the scheme depicted in Figure 2. The spectra show an increase in the aromatic carbon fraction relative to the aliphatic carbon fraction with increasing depth (i.e. temperature). Aliphatic carbon structures are hydrogen rich and are largely responsible for the hydrocarbons that
are generated during natural and artificial maturation. The increase in carbon aromaticity with depth is due to loss of aliphatic carbons to hydrocarbon generation and to aromatization reactions. However, it is not possible to partition these losses between the two types of reaction without detailed material balances and elemental analyses. Nevertheless, by monitoring the aliphatic and aromatic carbons as a function of burial depth, limits can be placed on the capacity of source rocks to generate hydrocarbons at depth. Such information is difficult, if not impossible, to obtain by other methods. The NMR spectra in this example suggest that in the Wind River Basin, most of the volatile products (oil and gas) are generated down to a depth of about 3570 m. At greater depths there is not a sufficient fraction of aliphatic carbons remaining to generate hydrocarbons.

The aliphatic carbon region (0–90 ppm) shows partial resolution of at least two types of carbon (see Figure 1). These can be assigned to methylene carbons (CH$_2$) in long chains (30 ppm), and methyl groups (CH$_3$) attached to aromatic rings (ca. 20 ppm). Methylene carbons in branched and cyclic aliphatic structures are also counted with the methylene carbons at 30 ppm. The resolution is more noticeable in the spectrum of the sample at 3415 m. At greater burial depths, the spectra show a shift in position of the maximum of the aliphatic carbon resonance from 30 ppm for methylene carbons in long chains to that of the methyl groups attached to aromatic rings at ca. 20 ppm. Ultimately, these methyl groups would be the source of methane gas at very high maturity (Figure 2). Resonances at 300 and −50 ppm, most clearly seen in the 6041 m spectrum, are spinning sidebands.

There is a narrowing of the width of the aromatic resonance band (90–200 ppm) with increasing burial depth. This narrowing is indicative of an increase in the number of fused rings in the polynuclear aromatic moiety and of a lesser amount of substitution on the aromatic rings as alkyl side chains are cleaved during oil and gas generation. During maturation, cleavage of substituents bridging aromatic rings also initiate condensation reactions that yield larger aromatic cluster sizes. Aromatization of aliphatic carbons to produce larger more condensed aromatic ring structures would limit the number of substituents per aromatic carbon in the ring. The net effect of all these changes is to narrow the chemical shift dispersion, which results in a narrower aromatic resonance band. The general features of the NMR spectra as a function of burial depth in Figure 3 have been observed for maturation of petroleum source rocks$^{28}$ and coals during hydrous pyrolysis.$^{29}$

The CP/MAS $^{13}$C NMR spectra also show a resonance band at ca. 180 ppm for the outcrop sample. This band is attributed to carboxylate carbon functionality. During maturation, decarboxylation reactions occur liberating CO$_2$. The CP/MAS $^{13}$C NMR spectra in Figure 3 show that this carbon functionality has disappeared by the time that a depth of 2166 m is reached, illustrating that evolution of CO$_2$ occurs in the early stages of maturation.
During artificial maturation (pyrolysis), rapid evolution of CO₂ is observed at low temperatures and is thought to be a major contributor to crosslinking and retrograde reactions.\(^{(30)}\)

2.3.4 Nuclear Magnetic Resonance Evaluation of Source Rock Potential

The changes that are observed in the NMR spectra of source rocks as a function of burial depth are also observed in the laboratory when the sample is heated to a high temperature for short periods of time.\(^{(29,31)}\) As a result, an NMR spectrum can be used to evaluate a rock for its potential to produce liquid hydrocarbons during burial. An example is shown in Figure 4 for the case of an oil shale from Colorado and a sub-bituminous coal from Wyoming. The conversion data were obtained from a Fischer assay of the materials (see Oil Shale and Shale Oil Analysis). The most important factor controlling the generation of oil and gas is the hydrogen content of the organic matter. The Colorado oil shale is from a lacustrine depositional environment and has a highly aliphatic carbon structure; therefore, it has a high hydrogen content. It would be an excellent petroleum source rock, given the property relating to the geological conditions of burial depth and time. The Wyoming sub-bituminous coal is of a terrestrial origin. It has a more aromatic carbon content and therefore is hydrogen deficient relative to the Colorado oil shale. These characteristics are shown in the NMR spectra and they correlate well with the conversion data.

3 LIQUID-STATE NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM DISTILLATE FRACTIONS

Liquid-state NMR is unsurpassed as a spectroscopic technique for characterizing and quantifying the molecular structure and dynamics of monomolecular materials. In the study of complex materials such as petroleum, the technique is most often used for characterization and quantification of the structure of the various petroleum distillate fractions, including residues.\(^{1\text{H}}\) and \(^{13}\text{C}\) NMR have been used to study naphtha and gasoline,\(^{(32–34)}\) middle distillates,\(^{(35,36)}\) jet and diesel fuels,\(^{(37–41)}\) light gas oil,\(^{(42)}\) heavy oils,\(^{(43–45)}\) light crudes,\(^{(46)}\) waxes,\(^{(47)}\) and residue and heavy ends, including asphaltene and asphalts.\(^{(48–53)}\) Most of the studies involved the use of one-dimensional NMR spectral techniques. However, studies have included the use of two-dimensional (2D) NMR spectroscopic techniques, which facilitate the spectral interpretation of complex mixtures. Compared to gas chromatography and mass spectrometry, a major advantage of NMR spectroscopy is that the technique can also be applied to fractions that have boiling points greater than 550 °C.

3.1 Experimental Procedures and Instrumentation

Petroleum crudes are complex solutions of thousands of different paraffinic, aromatic and heteroaromatic molecules. Neither NMR nor other spectroscopic techniques directly provide enough information fully to delineate the individual components present in the whole crudes. Thus, as with other techniques, fractionation of the crude oil is desirable to reduce the complexity of molecular types in a sample and to obtain meaningful information about the molecular structure from an NMR spectrum. The first fractionation is usually distillation, which yields products of the petroleum crude such as gasoline, kerosene and vacuum gas oils. The distillate products are listed in Table 2. The light distillates can also be easily characterized and quantified by mass spectrometry, other spectroscopic techniques such as infrared, and chromatographic methods. The light as well as heavy distillates can be separated further into saturates, olefins and aromatic structural groups, using solvent extraction and various

chromatographic techniques. Because individual compounds cannot be easily identified in the fractionated samples, recourse must be made to approximate (average) structural characterization methods using information obtained from NMR, elemental and average molecular weight (AMW) data.

Petroleum fractions for NMR studies are usually dissolved in CDCl₃ containing a small amount of tetramethysilane (TMS) as an internal reference for both ¹H and ¹³C chemical shift measurements. Because of the high sensitivity of present-day NMR spectrometers, only a few milligrams of sample are needed for a ¹H spectrum and approximately 100 mg for a ¹³C spectrum. To obtain quantitative data from a ¹³C NMR spectrum, it is often necessary to add a small amount of the relaxation reagent, chromium(III) acetylacetonate, to a CDCl₃ solution of a distillate fraction.

Almost all experiments are performed using a Fourier transform NMR spectrometer at frequencies ranging from 100 to 400 MHz for ¹H and from 25 to 100 MHz for ¹³C. Many of the spectrometers manufactured today are multinuclear, almost fully automated and computer controlled. In addition, many can be programmed to conduct two- and three-dimensional spectral data acquisition.

3.2 One-dimensional Nuclear Magnetic Resonance

3.2.1 ¹H Nuclear Magnetic Resonance

The hydrogen (¹H) resonance signal is the most easily detected signal of any of the elements, and the area of the ¹H resonance quantitatively represents the number of hydrogens of a given type within a molecule. Two disadvantages of the ¹H NMR technique for investigation of complex mixtures are the spin–spin scalar coupling of adjacent hydrogens in a molecule and the small chemical shift range for the different hydrogen types (0–15 ppm). The scalar coupling results in splitting of a given hydrogen type into multiple peaks. The splitting pattern (multiplicity) is useful diagnostically for determining the structural groups adjacent to one another in molecules. However, in complex mixtures of molecules the splitting patterns of the various hydrogens overlap one another, resulting in the loss of resolution and information related to the coupling of adjacent hydrogen groups. This loss of resolution, together with chemical dispersion (many hydrogen types in the different compounds with similar but not equal chemical shifts), results in a broad envelope of resonances for the methyl, methylene, methine, olefinic and aromatic hydrogen types.

Figures 5 and 6 show the 400 MHz ¹H spectra of a regular grade gasoline and of an asphalt, respectively. The high resolution of the resonances peaks observed for the ¹H spectrum of the gasoline relative to asphalt is due to the relatively low molecular weight and lower number of compounds found in gasoline. The peak at 0 ppm is the chemical shift reference, TMS. The peak at 7.24 ppm results from a small residue of CHCl₃ in CDCl₃. The spectra shown in Figure 5 can be divided into three major hydrogen types: aliphatic, olefinic, and aromatic. The aliphatic hydrogens have chemical shift values ranging from 0.5 to 4.0 ppm. This region can be further divided into resonances associated with the methyl, methylene and methine functional groups. The chemical shift range from 4.0 to 6.0 ppm represents the resonances due to olefinic hydrogens. The resonance profile in this region can be used to determine the types of olefin present. The aromatic hydrogens lie in the chemical shift range from 6.6 to 8.3 ppm, which can be divided further into hydrogens associated with mono-, di-, and tri-aromatic ring systems. The ¹H chemical shift ranges for the various
NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM

Figure 6 400 MHz $^1$H NMR spectrum of an asphalt.

Hydrogen types in hydrocarbons are given in Table 3. The interpretation of the $^1$H spectrum is further complicated if there are significant concentrations of aliphatic groups adjacent to heteroatomic groups containing nitrogen, oxygen and sulfur. Thus, before attempting to assign the peak in a $^1$H spectrum, some knowledge of elemental and functional group composition is desirable. Conclusions can be drawn from $^1$H NMR data about the average carbon skeleton if one assumes a definite H/C ratio for the aliphatic constituents. However, the combined use of $^{13}$C and $^1$H NMR data is the preferred method.

Several instrumental parameters must be established for reliable quantification of the NMR integration data. Typically, long relaxation delay times between 5 and 20 s, with a relatively small pulse angle ($<40^\circ$), are used to acquire $^1$H Fourier transform (FT) spectra. Good integration of the data can easily be obtained, but depends on having correct phasing and a flat baseline. Absolute determination of the hydrogen content by NMR is not often performed, but can be accomplished by adding an accurately weighed pure compound with a single $^1$H resonance peak to the sample of interest.$^{55,56}$ The chemical shift of this reference compound must be in a region which does not interfere with the integration of the hydrogens associated with the sample.

Relative integration values from a $^1$H spectrum are typically obtained for the different hydrogen types. Because the resonance signals for the total aromatic and aliphatic hydrogen types are widely separated, reasonably good accuracy and precision of the integration can be achieved. However, within the aromatic and aliphatic hydrogen regions, where only partial separation of hydrogen types are observed, the integration of the hydrogen types is less accurate and depends on the chemical shift range assigned to the particular hydrogen type. High field spectra for some samples can increase the resolution between hydrogen types and thus provide better integration values. 2D NMR spectra can also provide good resolution in some cases, but accurate integration can be more difficult.

peaks in each spectrum centered at 78 ppm are due to the carbon atom coupled to the deuterium atom of the solvent CDCl₃. The olefinic carbons, if present, would have chemical shift values which overlap the aromatic carbon chemical shift range and are not easily identified in a one-dimensional NMR spectrum. In this case, the ¹H spectrum is preferred for identification and quantification of olefins. However, with advanced techniques such as 2D C–H correlation experiments, olefinic carbons can be identified and quantified (see section 3.3). Depending upon the petroleum distillate and subfractions of the distillates, the aromatic and aliphatic region can be further subdivided into different carbon types using various spectral editing and 2D NMR techniques (see sections 3.2.3, 3.3, and 3.7.2). These methods can be used to resolve tertiary and quaternary aromatic carbons and the methyl, methylene, methine, quaternary aliphatic carbons. In the asphalt spectrum (Figure 8) only the methyl (14 ppm) and methylene carbons (23, 30 and 32 ppm) of straight chain alkanes are readily identifiable.

Table 3 lists the carbon-13 chemical shift for various carbon types in hydrocarbons.

The nuclear parameters which affect the quantitation of the carbon resonance signals are the ¹³C spin–lattice relaxation time and the nuclear Overhauser enhancement effect (NOE). Carbon relaxation times are considerably longer than for hydrogens. In addition, aromatic quaternary carbons (bridgehead or from alkyl-substituent) in a molecule have much longer relaxation times relative to other carbons with attached hydrogens. To shorten and equalize the relaxation times among the various carbons, a relaxation reagent is often added to the sample. The most often used relaxation reagent is chromium(III) acetylacetonate at a concentration of about 0.05 M. Even with this reagent, instrumental parameters such as a small pulse angle of <90° and a pulse sequence delay of 5–10 s are used. The NOE on the various carbons can differ significantly but can be reduced using an inverse gated decoupling pulse sequence. This pulse sequence minimizes the NOE of all carbon signals, but because the signal enhancement by this effect is lost, time averaging processes must be increased to achieve a good S/N ratio. As with ¹H NMR, reliable integration of a carbon spectrum depends on correct phasing and a flat baseline.

### 3.2.3 Spectral Editing

NMR spectra of petroleum distillates are often recorded with the objective of elucidating the molecular structural characteristics of the sample in an effort to understand better its physicochemical properties and to monitor changes in process conditions. The usual approach involves subdividing the conventional ¹H and ¹³C NMR spectra into chemical shift regions, each of which is

---

**Figure 7** 100 MHz ¹³C NMR spectrum of a regular grade gasoline.

**Figure 8** 100 MHz ¹³C spectrum of an asphalt.

¹³C spectra of a regular grade gasoline and an asphalt are shown in Figures 7 and 8. Because there are fewer compounds, a large ¹³C chemical shift range and broadband decoupling of the hydrogens, the resonance peaks, which each represent a single carbon type, are well resolved for the gasoline compared to those for the asphalt spectrum. The lower resolution and broader peaks in the asphalt are the result of chemical shift dispersion caused by the many compounds and shorter relaxation times for the carbon atoms. The ¹³C spectrum of a hydrocarbon has two distinct chemical shift regions. The chemical shift for the aliphatic carbon-types ranges from 5 to 50 ppm and the aromatic carbons range from 100 to 150 ppm. Carbons adjacent to heteroatoms (nitrogen and oxygen) are often resolved in many light petroleum distillates. Phenolic and carbonyl carbons have chemical shifts ranging from 150 to 210 ppm, oxygenated aliphatic carbons have a range of 40 to 60 ppm. The three
assumed to be associated with a single type of hydrogen or carbon substructure. If suitable experimental precautions are taken, integration yields the relative abundance of the different ¹H and ¹³C aromatic and aliphatic structural types. However, chemical shift–structure relationships are limited in scope because of the ambiguities associated with determining the chemical shift range for many different hydrogen and carbon types in a fossil fuel. It is difficult to know where to subdivide spectra in such a way that structural inferences are both detailed and valid. Too large or too small a range will increase or decrease the relative abundance of the different structural types and increase the uncertainty of structural inferences. In addition, structural information such as the hydrogen connectivity and carbon multiplicity of the structural groups is lost when using conventional ¹H and ¹³C experimental techniques for complex mixtures.

An alternative approach to quantify the NMR spectral data of any petroleum fraction into carbon types (CHₙ, n = 0–3) is to use spectral editing techniques, i.e. separation of ¹³C spectra into methyl (CH₃), methylene (CH₂), methine (CH), and nonprotonated or quaternary (C) carbons. The distortionless enhancement by polarization transfer (DEPT), gated spin-echo ¹³C NMR (GASPE), and the spin-echo broad-band off-resonance decoupling (SEBBORD) are a few of the techniques that have been developed to regain the carbon multiplicity information and to define more precisely the chemical shift range for different carbon types in a complex molecule or mixture of molecules. These methods are based upon obtaining a series of spectra by modulating the signal intensities of the CHₙ group as a function of either the ¹H pulse width, θ (DEPT) or the ¹³C–¹H scalar spin-coupling characterized by a spin-coupling constant, JCH (GASPE). A linear combination of these spectra results in edited spectra of the specific carbon types (DEPT CHₙ, n = 1–3 and GASPE CHₙ, n = 0–3). Figure 9 shows the conventional ¹³C spectrum and the ¹³C edited DEPT spectra for the various carbon types in the saturate fraction obtained from the 200–425 °C distillate cut from the Cerro Negro heavy petroleum. Also shown is the quaternary only (QUAT) ¹³C spectrum. The spectra shown can be integrated to give the relative fractional amounts of the various carbon types. From a knowledge of the fractional amounts of carbon types, a number of average molecular structural parameters can be determined (see section 3.4).

**3.3 Two-dimensional Nuclear Magnetic Resonance**

In spectra which are inherently crowded, such as those of complex mixtures of different hydrocarbons, overlapping resonances of the various carbon types can often be separated and/or identified by introducing an additional dimension to the normal intensity versus chemical shift (frequency) representation of an NMR spectrum. The introduction of a second frequency dimension can be either a second chemical shift or a scalar-coupling parameter. The application of 2D NMR techniques to fossil fuels is relatively new, but their value is becoming increasingly apparent. The application of 2D NMR to the complex mixtures of chemical types encountered in such fossil fuel liquids as shale oils, coal liquids, or petroleum have been reported. The application of
2D methods to fossil fuels has been limited to oils and distillates, since heavier fractions, such as asphaltenes, usually do not give sufficient resolution even at high field.

In principle, two classes of 2D experiments exist: $J$-resolved (2D-$J$) and correlated 2D spectra. The first is characterized by one frequency axis containing the coupling (multiplicity) information and by another frequency axis containing the chemical shifts. In a second type, both frequency axes contain chemical shift information. The connection between the two frequency axes is through scalar coupling (homonuclear $[^1H-^1H]$ as well as heteronuclear $[^1H-^{13}C]$) or through dipolar coupling.

Figure 10 shows a homonuclear ($[^1H-^1H]$) 2D-$J$ spectrum (70) of an aromatic petroleum solvent (PETSOL), which mainly consists of a mixture of alkyl benzenes. The $x$-axis represents the $^1H$ chemical shift of the alkyl hydrogens, the $y$-axis the coupling (multiplicity) information, and the $z$-axis the intensity. The multiplicity reflected in the ($^1H-^1H$) coupling gives information on neighboring $^1H$ group interactions. Peak 7 shows that the methyl hydrogens are split into a triplet, which indicates the methyl group is adjacent to a group containing two hydrogens (the adjacent methylene group in the alkyl substituent). The three-dimensional presentation of the data can also be done in the form of a contour plot, (70) as shown in Figure 11.

Homonuclear correlated 2D NMR data from a correlation spectroscopy (COSY)-90 experiment (72) are presented in Figure 12 for a monoaromatic diesel fraction. The contour format is employed. Both horizontal and vertical axes pertain to the $^1H$ chemical shift. All $^1H$ groups contribute to intensity on the diagonal. Off-diagonal peak intensity arises when two $^1H$ groups of different chemical shifts are coupled. The relationship between regions in the $^1H$ NMR spectrum can be interpreted as follows: (72) peaks 1 and 20 are coupled and belong to the 1-methylindan ring: 2–19, isopropyl; 3–9, indan ring: 4–17, 1-methyltetralin ring: 5–11, tetralin ring; 7-(13/12)-23, propyl; 7-(13/14)-(15/16)-22, butyl; 8, $a$–OH$_3$ not coupled, and 10–21, 2-methyltetralin ring.

The 2D heteronuclear ($^1H-^{13}C$) correlation (HETCOR) spectrum (71) of an aromatic fraction separated from a high-speed diesel fuel sample is shown in Figure 13. The 2.0–3.5 ppm region of the $^1H$ NMR spectrum is shown along the vertical axis, whereas the horizontal axis shows the $^{13}C$ DEPT $135^\circ$ spectrum of the carbons in the aliphatic region (5–50 ppm). In the DEPT spectrum, signals of the CH and CH$_3$ carbons appear as negative and those from CH$_2$ appear as positive peaks. The signals between 18 and 20 ppm in the $^{13}C$ NMR spectrum are due to the methyl substituents of the aromatic carbons. These signals are used to assign the $^1H$ NMR region from 2.0 to 3.5 ppm to the hydrogens of the methyl group attached to an aromatic ring. Upon closer examination of the HETCOR spectrum, the $^1H$ region between 2.4 and...
3.0 ppm contains signals due to both $\alpha$-CH$_2$ and $\alpha$-CH$_3$ substituents on the aromatics.

A stacked plot of the HETCOR experiment$^{(69)}$ performed on a fossil fuel liquid containing both aromatic and olefinic material is shown in Figure 14. The 1D-$^{13}$C spectrum (vertical axis) shows complete overlap of the two types of sp$^2$ carbons. The 1D-$^1$H spectrum (horizontal axis), however, gives complete separation of the aromatic and olefinic hydrogens. Thus, through the use of the 2D/HETCOR spectrum, the olefinic $^{13}$C peaks can be assigned based upon the splitting pattern observed in the $^1$H spectrum. Several of the $^{13}$C peaks are identified as specific types of olefin (shown in Figure 14). The unlabeled peaks are unassigned protonated aromatic carbons.

The preceding illustrations of the spectral editing and 2D NMR methods represent a few of the many techniques that are available to the NMR spectroscopist in an effort to identify and quantify carbon types in complex materials.

### 3.4 Average Molecular Structural Parameters

Detailed compositional characterization of petroleum fractions is extremely important, but has proved to be quite difficult and time-consuming. For these reasons, procedures have been reported which describe a particular fraction in terms of a hypothetical molecule.$^{(73-75)}$ The methods of average molecular structural determination usually incorporate results of elemental analysis, $^1$H and $^{13}$C NMR spectroscopy, and average molecular weight (AMW) determination from vapor pressure osmometry (VPO) to define the structural parameters of an average
molecule. Table 4 lists some of the average parameters which are generally determined for petroleum fractions. It is important to realize that these average parameters are weighted averages for certain properties of the sample and may not represent actual structures present in the petroleum fraction. There is little evidence to indicate that complex mixtures exhibit the chemical and physical behaviors predicted by a single hypothetical structure. However, it can be reasoned that the narrower the distillation cut, the more the “average molecule” represents the chemical and physical properties of the fractions. There are many hidden assumptions in calculating the average molecular structure of a petroleum fraction. One important major assumption is that all alkyl groups are present as substituents on aromatic rings. In solid materials, this is probably a good assumption (see section 4.1).

3.5 Applications

#### 3.5.1 Average Molecular Weight

Characterization of oil fractions using average molecular parameters obtained by quantitative NMR analysis is often used to monitor the changes in composition at various stages of conversion processes and for simulating thermophysical properties of crude oil, such as phase equilibria. To simulate the thermophysical properties of crude oil, accurate values for the AMW of the oil distillate fractions are required to establish a relevant equation of state for the fluid. The data obtained through VPO are sometimes questionable.\(^{(78)}\)

NMR structural analysis models can be used to obtain AMWs of high-boiling aromatic fractions.\(^{(78)}\) A model using a \(^{13}\)C spectral editing technique has been found to be particularly reliable. Tests on 17 narrow high-boiling aromatic fractions of a North Sea crude oil gave very good agreement with mass spectrometry data. In another study, a simple algorithm based on data from NMR spectra gives AMW values consistent with VPO values for different fractions as distillates, residues or asphaltenes.\(^{(79)}\)

#### 3.5.2 Characterization of Chemical Class in Petroleum Distillates

Spectral editing techniques, DEPT and QUAT, have been used to characterize and quantify several saturate fractions from a Cerro Negro heavy petroleum crude. Spectral editing techniques, DEPT and QUAT, have been used to characterize and quantify several saturate fractions from a Cerro Negro heavy petroleum crude.\(^{(37)}\) Saturate hydrocarbon fractions have been obtained from the 200–425, 425–500 and 550–700°C distillate cuts and the >700°C residue. The average molecular structural parameters calculated from the NMR data are given in Table 5. Quantitative \(^{13}\)C NMR subspectral analysis has provided detailed molecular structural information on saturate fractions that have atmospheric equivalent structural parameters.

boiling points above the temperature for effective use of the GC/MS and ASTM (American Society for Testing and Materials) D-2786 mass spectral techniques. For the 200–425 and 425–550 °C distillate fractions, the NMR data correlate reasonably well with mass spectral data.

Conventional \(^{13}\)C and \(^{1}H\) NMR and spectral editing technique GASPE were used to provide detailed quantitative information regarding the abundance of major and minor alkanes and olefins in jet and diesel fuels from a Fischer–Tropsch syn crude. \(^{88}\) The jet fuel consisted primarily of \(n\)-alkanes (87 wt%), while branched alkanes with, on the average, 12 carbon atoms per molecule and one \(CH_3\) branch per molecule, represent another 9 wt%. Olefins represent nearly 4 wt% of the sample. From \(^1H\) and \(^{13}C\) NMR spectra of the olefins, the \(cis\) and \(trans\) isomers, as well as the position of the double bond, could be distinguished. Similar results were found for the diesel fuel in which the average number of carbon types per molecule was found to be approximately 15.

The branched and cyclic alkanes from the saturate fractions from diesel and kerosene fuels were characterized using the \(^{13}\)C NMR technique, GASPE, to determine the fractional abundance of \(CH_n\) groups. \(^{81,82}\) The \(n\)-alkane and branched plus cyclic alkanes were separated from each other using silica chromatography and urea clathration. The NMR data were used in calculating several average structure parameters, which included: number of branches per molecule, number of branches per branched molecule, number of branches per cyclic molecule, and number of rings per cyclic molecule.

A direct and fast method for estimating the aromatic carbon content in hydrofinished and hydrocracked types of base oils using \(^1H\) NMR spectroscopy was reported by Sarpel et al. \(^{85}\) In developing the method, the 2D HETCOR spectral analysis technique was used, which facilitated the estimation of quaternary and bridgehead aromatic carbons from the \(^1H\) NMR spectrum. Using derived equations, the complete assignment of the \(^1H\) NMR spectrum can be made, from which the aromatic content can be determined for the base oils. The methodology is highly useful for routine quality control analysis where a large number of base oils are required to be analyzed in a limited time. In principle, the method should easily be extended to other heavier ends like vacuum gas oils.

Bansal et al. \(^{71}\) reported the methodology for the estimation of total aromatics and their distribution as mono- and polynuclear aromatics in diesel-range fuel products. The method is also based on the detailed analysis of the \(^1H\) NMR spectrum. Advanced NMR techniques such as DEPT and 2D HETCOR were applied for the unambiguous assignment of the \(\alpha\)-substitution on the aromatic ring in the \(^1H\) NMR spectra (2.0–3.5 ppm region). The proposed \(^1H\) NMR-based method correlates very well with the standard HPLC(IP-391/90) and mass spectrometric-based techniques.

1D and 2D NMR methods can be used to elucidate the structural characteristics of the monoaromatic fractions from petroleum and synthetic fuels. \(^{72}\) Spectral assignments are supported by a range of NMR information, including \(CH_n\) types \((n = 0–3)\), \(^1H\) and \(^{13}C\) chemical shifts, \(^1H–^{13}C\) and \(^1H–^{1H}\) resonance connectivities, and \(^1H\) multiplicity. From the information provided by the various NMR techniques, the average number of \(\alpha-CH_3\), \(\beta-CH_3\), \(\gamma-CH_3\) groups per molecule can be calculated and a range of specific structures can be identified. Overall, the structural data are sufficient to identify similarities and differences for the monoaromatic fractions from different Australian petroleum sources.

### 3.5.3 Gasoline Octane Number

The octane number of a gasoline is a function of its chemical composition and therefore should correlate with the hydrocarbon types present. Mühle et al. \(^{32}\) reported a correlation between the reformed gasoline chemical composition and its research octane number (RON) determined by the standard ASTM method (D2699). Using \(^1H\) NMR spectral data to quantify the various hydrocarbon hydrogen types in 62 gasoline samples, they obtain the following linear regression relationship, Equation (1)

\[
\text{RON (NMR)} = 92.37 + 0.30H_A + 0.31H_B - 0.87H_C - 0.35H_D
\]

where \(H_A\) is the percentage of aromatic ring hydrogens, \(H_B\) is the percentage of \(\alpha\)-aromatic \(CH_3\) hydrogens, \(H_C\) is the percentage of paraffinic CH hydrogens, \(H_D\) is the percentage of paraffinic \(CH_2\) hydrogens.

The method gives a satisfactory level of accuracy and is suitable for determining the octane number of gasoline samples generated in the laboratory when small sample quantity prevents use of the standard method.

### 3.5.4 Diesel Cetane Number

The cetane number (CN) measures the ignition quality of a diesel fuel. The effect of hydrocarbon type composition of the fuel on the ignition quality is qualitatively well-known. However, analytical methods to identify the amount of each hydrocarbon are time-consuming and thus prevent the establishment of models to represent quantitatively the effects of hydrocarbon type on ignition quality. Gül er and Glavincevski \(^{84}\) developed a \(^1H\) NMR method to predict the CN of diesel fuels from the carbon-type structural composition. Based on the carbon-type composition of 67 fuels, the CN can be predicted very well with the standard HPLC(IP-391/90) and mass spectrometric-based techniques.
using an expression of the functional form, Equation (2)

\[
CN = B_0 + \frac{B_1}{C_A} + \frac{B_2}{C_A^2} + (B_3C_a + B_4 \ln C_a)
+ (B_5C_2 + B_6C_2^2) + (B_7C_3 + B_8C_3^2)
\] (2)

where \( C_A \) is the number of aromatic carbons, \( C_a \) is the number of carbons at the \( \alpha \)-position to aromatic rings, \( C_2 \) is the number of \( \text{CH}_2 \) CH carbons including \( \beta \)-CH\(_2\), \( \gamma \)-CH\(_2\) and \( \beta \)-CH\(_3\) to aromatic rings, \( C_3 \) is the number of \( \text{CH}_3 \) carbons including terminal and branched and \( \gamma \) to aromatic rings, and \( B_0 = 24.3848; B_1 = -286.728; B_2 = 587.3567; B_3 = 1.5227; B_4 = -15.882; B_5 = 0.9778; \)
\( B_6 = 0.0047; B_7 = -0.2835; B_8 = 0.002. \)

The constants, \( B_i \), are determined by a multiple regression analysis fit of the data. The accuracy of the correlation is better than the accuracy of the cetane engine measurement on the basis of the spread of CNs determined by a number of standard cetane rating engines.

### 3.5.5 Lubricant Base Oils

Base oils are lubricant components which provide a fluid layer to separate dynamic surfaces. The fluid layer removes heat and wear particles while keeping friction at a minimum. The properties of base oils depend on the chemical composition and structural characteristics of hydrocarbon molecules present in the matrix. NMR techniques have been used to understand the carbon and hydrogen distribution in base oils in terms of average structural parameters (see Adhvaryu et al.(86) and the references they cite). These parameters, in principle, can be correlated with the basic properties required as specification for lube oil formulations. Using \(^{13}\text{C}\) NMR, Singh et al.(86) studied industrial base oils refined from light and intermediate viscosity distillates and an aromatic-rich oil. A number of NMR average structural parameter values (Table 6) were correlated with several physicochemical characteristics of the lube base stocks (Table 7). Reasonable good correlations were determined for the percent aromatic carbon with the weight percent of sulfur, aniline point, the UOP characteristic factor, and the viscosity index. The study reveals that NMR could be

a potent technique for predicting various physicochemical properties which are used for base oil specifications (see also section 4.2).

4 SOME APPLICATIONS OF NUCLEAR MAGNETIC RESONANCE TO PETROLEUM PROCESSING

4.1 Average Molecular Structures Using Solid-state Nuclear Magnetic Resonance

The observed NMR signals represent all the carbons in the sample and cannot distinguish whether these carbons are in a single molecular entity or in a mixture of many different molecular types. Sometimes it is advantageous to construct an average molecule from average molecular structural parameters to monitor changes that result from varying process conditions, feedstocks, or other variables. In petroleum fractions, in which aliphatic and aromatic carbons, for example, exist in separate compounds, an average molecule does not represent the average properties of the mixture and is of little value in studying changes in process conditions. In solids such as coals, however, the situation is different because the concentration of paraffins is small. Any aliphatic carbons present are usually assumed to be attached to an aromatic cluster so that an average molecular representation can be constructed and the change in process conditions can be monitored.

Solum et al.\(^{87}\) have devised an NMR procedure for calculating a number of molecular parameters that are useful in petroleum processing that involves solid or insoluble materials. DD relaxation data and integrated intensities of selected chemical shift ranges in a CP/MAS NMR spectrum are used to calculate 12 basic structural parameters, from which an additional eight structural parameters can be derived. A list of representative chemical shifts and carbon structures is given in Table 1. Definitions of the integrated areas are listed in Table 8. The superscripts on the areas refer to the chemical shift range in parts per million over which the integrals are evaluated. NMR structural parameters and additional lattice parameters derived from these data are given in Table 9. The procedure for calculating the structural parameters in Table 9 is from Solum et al.\(^{87}\)

Storm et al.\(^{88}\) used this procedure to develop molecular representations of petroleum asphaltenes and to develop correlations that predict fouling due to sludge formation in visbreaking and hydrocracking processes. Sludge formation occurs when asphaltenes flocculate. Therefore a better understanding of asphaltene molecular properties could lead to a better understanding of the mechanisms of coking and sludge formation in refinery operations. However, it should be stressed that asphaltenes are defined on the basis of solubility and that an asphaltene molecule per se does not exist. Asphaltenes are a mixture of strongly interacting molecules having colloidal properties. Therefore using an average asphaltene structure to represent a mixture is somewhat dubious and should be used with caution.

Nevertheless, Storm et al.\(^{88}\) derived molecular representations of Ratawi and Alaska North Slope asphaltenes. These differed from other “average structure” calculations in that a molecular weight is not independently measured in order to calculate the average molecule. Instead the procedure automatically provides estimates of the AMWs that are consistent with independent determinations. The Ratawi asphaltenes are represented by four condensed rings with four side chains.

and one connecting bridge, whereas the Alaska North slope asphaltenes are represented by four condensed rings with three side chains and one connecting bridge.

Sludge formation during heavy oil upgrading is a problem in many petroleum refinery processes. Often a soft coke-like substance forms during visbreaking and hydrocracking processes. This limits the severity of the conversion because it accumulates in downstream equipment, causing fouling. Because more petroleum operations use the bottom-of-the barrel for upgrading, methods to predict the production rate of sludge formation from chemical characteristics of the crude oil are of great importance. Storm et al.\(^{88}\) found that the propensity of a feedstock to form sediment is related to a parameter which characterizes the degree of condensed polynuclear aromaticity of the resid. The polynuclear aromaticity is defined as the fraction of aromatic bridgehead carbons. This value can be obtained from NMR data using the formulas given in Table 9. The propensity to form sludge is higher the more the polynuclear aromatic hydrocarbon cores are highly substituted with alkyl groups. The degree of substitution can also be obtained from NMR data using the formulas in Table 9.

When applying the analytical procedure just described, it should be pointed out that, depending on the material under investigation, not all carbon types are necessarily present in the sample, and, therefore, will not be observed in the normal CP/MAS spectrum. For example, the procedure described was derived for characterization of coals. Phenolic and carboxylate carbon structures are generally part of the organic structure of these materials. In asphaltenes, these carbons are usually absent, or in low abundance and can be ignored.

### 4.2 Predictive Property Correlations

As the world continues to deplete its supply of high-quality crude oil, heavy crude oils that contain molecules of higher molecular weight and are more aromatic and contain more heteroatoms are being processed to a greater extent than previously. To process these heavy oils, their thermodynamic and transport properties must be known. Methods to estimate these basic parameters generally use normal boiling points and liquid densities at 15.6°C (60°F),\(^{90}\) Many of these correlations are not applicable to fossil fuels that contain a significant number...
of heteroatoms. In addition, the liquid densities and boiling points that are needed may be experimentally inaccessible.

NMR can be used effectively to provide molecular structure parameters for use in predictive property calculations. Schwarz and Prausnitz used NMR to develop a correlation for thermodynamic properties of heavy fossil-fuel fractions. Elemental analyses provide the relative abundances of C, H, O, N, and S atoms. An NMR spectrum is used to distinguish between: hydrogen bonded to an aromatic carbon, hydrogen bonded one carbon away from an aromatic ring, hydrogen bonded to a nonterminal carbon further than one carbon away from an aromatic ring, and hydrogen bonded to a methyl group that is not bonded to an aromatic ring. Infrared spectroscopy was also used to distinguish between ether and hydroxy oxygen and to distinguish between amines and other nitrogen groups.

Schwarz and Prausnitz give detailed example calculations for converting raw characterization data to specific characterization parameters used in their perturbed-hard-chain equation of state. The procedure is not intended for calculations on conventional fossil fuels, where experimental data on boiling points and properties included smoke point, aromatics content, hydrogen content, heat of combustion, freezing point and specific gravity. For diesel fuels in the range 230–320°C, the properties included pour point, cloud point, hydrogen content, aniline point, specific gravity, diesel index, and cetane index. The results are summarized in Tables 10 and 11. Of particular note is that the relationships all have the same form and use the same type of analytical information.

4.3 Determination of Hydrogen Consumption During Processing

In the 1990s there has been a significant increase in residuum hydroconversion in refineries throughout the world. To a large extent, this expansion was derived from expectations that the spread in market values between high-sulfur fuel oil and light transportation fuels would increase to support the investments required for these conversion facilities.

Residuum conversion involves increasing the hydrogen-to-carbon (H/C) ratio and decreasing the molecular weight of the distillate products. However, because of the hydrogen imbalances, either carbon is rejected or hydrogen is added to achieve a desired product state. For those processes that involve hydrogen addition, NMR can be used effectively to determine the types of reaction that consume hydrogen under a given set of process conditions.

Finseth et al.\(^\text{95}\) proposed a method to monitor the changes in hydrogen utilization during coal liquefaction. The same approach can be used to study the role of hydrogen during residuum upgrading.\(^\text{96, 97}\) This method incorporates analytical methods that are readily available. In the method of Finseth et al.,\(^\text{95}\) the total hydrogen incorporated in the products during conversion is given by Equation (4)

\[
\Delta H_T = \Delta H_{\text{hyd}} + \Delta H_{\text{NOS}} + \Delta H_{\text{Cl},-\text{C}_4} + \Delta H_{\text{matrix}} \tag{4}
\]

where \(\Delta H_T\) is the total hydrogen incorporated, \(\Delta H_{\text{hyd}}\) is the hydrogen incorporated by hydrogenation, \(\Delta H_{\text{NOS}}\) is the hydrogen associated with heteroatom removal, \(\Delta H_{\text{Cl},-\text{C}_4}\) is the hydrogen associated with hydrocarbon gas production, \(\Delta H_{\text{matrix}}\) is the hydrogen incorporated in nonvolatile solid and liquid products owing to alkyl bond scission.

Thus, measurement of hydrogen incorporation during processing is reduced to measuring \(\Delta H_T\) by elemental analysis, measuring \(\Delta H_{\text{hyd}}\) by \(^{13}\text{C}\) NMR aromaticity measurements in the solid and liquid reactants and products, and measuring \(\Delta H_{\text{Cl},-\text{C}_4}\) and \(\Delta H_{\text{NOS}}\) by quantitative gas analyses. The term \(\Delta H_{\text{matrix}}\) is then determined by difference. If this term is negative, hydrogen is liberated because of condensation reactions. If \(\Delta H_{\text{matrix}}\) is positive, then thermolysis reactions consume hydrogen during liquefaction.

The method assumes that, on average, one hydrogen atom is incorporated into the organic product for every heteroatom removed from the feed material; hydrogenation consumes one hydrogen atom for every carbon atom reduced (each 0.01 change in aromaticity); and two hydrogen atoms are consumed per mole of light hydrocarbons formed. The rationale for these assumptions is discussed in greater detail by Finseth et al.\(^\text{95}\) and by Beret and Reynolds,\(^\text{96, 97}\) who also used the method to determine hydrogen incorporation in petroleum residuum hydroconversion.

Beret and Reynolds\(^\text{96}\) applied this method to study residuum hydroconversion of three California residua processed at different severities using different sets of operating variables such as temperature, pressure, residence time, hydrogen circulation route and catalyst. The approach yielded a detailed description of hydrogen incorporation during residuum hydroconversion. Character of the feedstock, processing conditions, and catalyst all affected how hydrogen was incorporated into the residuum matrix. Hydrogenation and hydrocracking reactions incorporated hydrogen equally at moderate process severities (343°C or 650°F). At higher severities (454°C or 850°F), the bulk of the hydrogen was used to cap radicals generated from cracking reactions. Thus, by a judicious choice of operating conditions, certain hydrogen incorporation reactions could be favored over others. The feedstock also influences how hydrogen was incorporated. With aromatic feedstocks, hydrogenation reactions compete for hydrogen equally with hydrocracking. With less aromatic feedstocks, hydrocracking dominates over hydrogenation reactions.

In another study, Beret and Reynolds\(^\text{97}\) used the method to study the effects of prehydrogenation on hydroconversion of Maya residuum. A Maya 343°C (650°F) residuum was prehydrogenated using a standard hydroprocessing catalyst. The 343°C (650°F) residuum of this product was then processed separately at selected conditions and the products analyzed to determine how hydrogen was incorporated during processing. The results were compared with direct hydroconversion. The distribution of hydrogen was dependent upon the type and severity of the process. In direct hydroconversion, about 25–30% of the total hydrogen was incorporated from heteroatom removal and hydrocarbon gas formation. The two-step process, which involved mild prehydrogenation, primarily incorporates hydrogen by hydrogenation reactions at the expense of \(\text{C}_4\) gas formation and cracking, particularly at low severity. At moderate severity, cracking reactions occur but are suppressed to some extent. The real benefit came from suppression of \(\text{C}_4\) gas formation.

4.4 Nuclear Magnetic Resonance Studies of Coking

Delayed coking is the most widely used petroleum residue conversion process in the world.\(^\text{98, 99}\) Although the process is about 60 years old, there are still many aspects of the chemical reactions taking place that are poorly understood. Of particular importance is the ability to predict product yield and quality from basic feedstock composition. Yield data are important for assessing process economics, and maximum conversion to liquid
NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM

products, primarily gasoline and distillate product is generally the main objective. Solid- and liquid-state NMR techniques can provide useful information about delayed coking processes similar to that described in the previous section. Complete NMR characterization (\(^{1}H\) and \(^{13}C\)) of a feedstock and delayed coking products, coupled with material balances, can be used to obtain the distribution of carbon and hydrogen atoms in a delayed coking process.

Rodriguez et al.\(^9\) used such an approach to study the delayed coking of a fluid catalytic cracker decanted oil in a pilot plant operation that simulated a conventional commercial operation. They demonstrate how to perform the material balance to reveal changes in the carbon and hydrogen distributions resulting from carbonization reactions during delayed coking. Rodriguez et al.\(^9\) found a significant increase in the number of aromatic carbons, which was due mainly to an increase in the number of quaternary aromatic carbons. This was interpreted as an increase in the extent of condensation reactions.

4.5 Process Kinetics

The reactions that occur during catalytic and thermal upgrading of crude oil are very complex and involve a large number of interacting species. In such complex mixtures, it is not possible to have a knowledge of all the interacting species. Consequently, lumped kinetics methods, wherein similar reactive species are grouped together to develop rate constants, have been developed to analyze reactions in complex mixtures.\(^1\) Lumping can be used to reduce the number of experiments required

![Figure 15](image.png)

**Figure 15** Assignment of carbon and hydrogen types to groups in regions of the \(^{13}C\) and \(^{1}H\) NMR spectra. (Reproduced with permission from M.R. Gray, *Ind. Eng. Chem. Res.*, 29, 505–512 (1990).\(^2\) Copyright (1990) American Chemical Society.)
to define the kinetic behavior of the reacting system, simplify the network of possible reaction paths, and reduce the overhead of analytical work required to define component-by-component compositions.

NMR spectroscopy provides a method for estimating the concentrations of a selected set of groups to be used in lumped kinetics as long as the sample is soluble in an appropriate solvent. Data from NMR analyses can be combined with elemental analyses to obtain concentrations of structural groups. The main structural groups that can be estimated by combining NMR with elemental analysis are shown in Figure 15. The spectra in Figure 15 are typical of heavy oils and illustrate the regions where signals appear from the different structural groups. The assignment of groups to the $^{13}$C NMR spectra involves some approximations that are due to overlapping peaks. The lack of sharp signals (except for paraffinic CH and CH$_2$) is due to the large number of isomeric compounds that have overlapping resonances. NMR provides a unique way of monitoring changes in the concentrations of these groups independent of molecular weight so long as the samples are soluble. Insoluble material can be analyzed by solid-state NMR, but less structural information can be deduced.

An example of the use of lumped kinetics in petroleum upgrading is that of Gray.$^{(100)}$ Data from thermal and catalytic hydrotreating of a Syncrude coker gas oil in a continuous-stirred reactor were used to study lumping of reaction kinetics based on structural groups. Feed and product compositions were described by a limited set of aliphatic and aromatic carbon groups, based on data from elemental analysis and $^1$H and $^{13}$C NMR spectroscopies. The study demonstrated that stoichiometric relationships or ratios between groups can be deduced from rate data, even in complex mixtures. These ratios could then be used to construct models for hydroprocessing. For example, the rate of heteroatom removal can be used to predict changes in the carbon aromaticity of the oil, which in turn, can be used to estimate the CN.

PETROLEUM AND LIQUID FOSSIL FUELS ANALYSIS

24

NUCLEAR MAGNETIC RESONANCE CHARACTERIZATION OF PETROLEUM

An oil shale can be defined as a compact rock of sedimentary origin with an ash content of more than 33% and containing organic matter that yields oil when destructively distilled, but not appreciably when extracted with ordinary solvents. This is an operational definition. There is no geological or chemical definition of an oil shale. The term is used mostly in an economic sense so that any shallow rock that yields a commercial amount of oil upon pyrolysis may be considered an oil shale. The key words are “commercial amount” because petroleum source rocks, which often contain only 1% organic matter, can produce commercial amounts of oil over geologic times. On the contrary, oil shales must have a large enough fraction of organic matter to be of economic interest. The organic matter content of an oil shale should be 2.5 wt%, just to provide the calorific requirements necessary to heat the rock to 500°C in order to produce shale oils by thermal decomposition of the organic matter. Below this amount of organic matter, the rock cannot be a source of energy because it takes more energy to heat the rock than can be derived from the produced shale oil. A lower limit of 5% organic matter is sometimes used to define a commercial deposit although such a limit is subject to change depending on prevailing economic conditions. Thus, an oil shale can be a petroleum source rock if subjected to the proper burial conditions over geologic time, but a petroleum source rock at shallow depths is not an oil shale because of the requirement of organic matter richness.

Oil shales occur worldwide, spanning geologic time from Cambrian to present, and were deposited principally in large freshwater lakes (lacustrine environment), shallow seas and continental shelves (marine environment), and in small lakes, bogs and lagoons associated with coal-producing swamps (paludal environment). Oil shale deposits occur in at least 50 countries and the estimated potential world supply of oil from shale is $5 \times 10^{12}$ barrels. Shale oil industries in Scotland, Australia, France, Russia, and China have been active over the years since about

An oil shale can be defined as a compact rock of sedimentary origin with an ash content of more than 33% and containing organic matter that yields oil when destructively distilled, but not appreciably when extracted with ordinary solvents. This is an operational definition. There is no geological or chemical definition of an oil shale. The term is used mostly in an economic sense so that any shallow rock that yields a commercial amount of oil upon pyrolysis may be considered an oil shale. The organic matter content of an oil shale should be $\sim 2.5$ wt%, just to provide the calorific requirements necessary to heat the rock to 500°C in order to produce shale oils by thermal decomposition of the organic matter. Below this amount of organic matter, the rock cannot be a source of energy because it takes more energy to heat the rock than can be derived from the produced shale oil. A lower limit of 5% organic matter is sometimes used to define a commercial deposit although such a limit is subject to change depending on prevailing economic conditions. Thus, an oil shale can be a petroleum source rock if subjected to the proper burial conditions over geologic time, but a petroleum source rock at shallow depths is not an oil shale because of the requirement of organic matter richness.

Oil shales occur worldwide, spanning geologic time from Cambrian to present, and were deposited principally in large freshwater lakes (lacustrine environment), shallow seas and continental shelves (marine environment), and in small lakes, bogs and lagoons associated with coal-producing swamps (paludal environment). Oil shale deposits occur in at least 50 countries and the estimated potential world supply of oil from shale is $5 \times 10^{12}$ barrels. Shale oil industries in Scotland, Australia, France, Russia, and China have been active over the years since about
the source of products similar to those obtained from petroleum. However, the discovery of petroleum in the United States in 1859, and elsewhere soon afterwards, caused the demise of the economic production of shale oil, and the situation remains much the same today. Limited but continued use of oil shale as an energy resource has been made since about 1909 in China and 1916 in Russia. In Brazil, a pilot plant has been in operation since 1982 and has produced over three million barrels of shale oil. Oil shale is being used for some power generation in Israel.

The Green River Formation in Colorado, Utah, and Wyoming, USA has been the most extensively studied oil shale formation in the world. A summary of core data and samples collected by the US Geological Survey has been published. Table 1 summarizes the number of Fischer assays performed on Green River Formation oil shales. During the 1970s, there was significant oil shale activity ongoing in the United States. Tracts of oil shale lands in the Green River Formation were leased for commercial development in 1974 and the decade between 1974 and 1984 represented the greatest activity ever in oil shale research in the US. Partly, this was caused by the oil embargo of 1973, the leasing of the oil shale tracts in Colorado and Utah in 1974, and the creation of the US Department of Energy in 1976. This activity spawned a variety of methods for analyzing oil shale. However, in the year 2000 oil shale activity has all but ceased in the US. Understandably, the plentiful supply and low cost of petroleum has suppressed the commercialization of oil shale and other fossil fuel conversion processes (tar sand processing and coal liquefaction).

The organic matter in an oil shale is mostly in the form of kerogen, which is defined as that fraction of the organic matter in a sedimentary rock that is insoluble in common petroleum solvents. Another fraction, bitumen, is defined as that fraction of the organic matter in a sedimentary rock which is soluble in common petroleum solvents. Kerogen constitutes the major portion of the organic matter (~90% or greater), and its insolvency is one reason why an oil shale must be heated to produce liquid products. Because of kerogen's insolubility, it has been very difficult to obtain information about the chemical structure and composition of kerogen. Compositional data can be acquired after first carrying out laborious and time-consuming procedures to remove minerals and to prepare kerogen concentrates. For an introduction to oil shales and kerogen, the reader is referred to books and reviews that are available.

### 2 OIL SHALE ASSAY METHODS

To evaluate the potential of an oil shale formation as a future source of liquid hydrocarbons, two important factors must be considered: (1) how much organic matter is in the formation, (2) how much of the organic matter can be converted to oil. The first factor relates to the total quantity of organic matter in the sediment, while the second factor relates to the quality or type of organic matter.

#### 2.1 Thermal Methods

##### 2.1.1 The Fischer Assay

Probably the single most important item of information about an oil shale is its potential to produce oil during heating. The traditional method for evaluating the potential oil yield of an oil shale is the Fischer assay [ASTM (American Society for Testing and Materials) method D-3904-80]. The Fischer assay consists of heating a 100 g sample of ~8 mesh (2.38 mm) particle size oil shale to 500°C at 12°C/min and maintaining this temperature for 40 min. During this heating cycle, hydrocarbon vapors are distilled from the rock and condense to form a shale oil. The material is collected, and its volume and weight and specific gravity are recorded. From these measurements, the oil potential is reported in gallons of oil per ton of shale (or liters per tonne, depending upon one’s preference for units). Obviously the greater this number, the greater the commercial viability of the formation.

The Fischer assay is strictly a specification test. It does not provide any information about the quality of the organic matter in the oil shale. Nevertheless, it is the benchmark for evaluating an oil shale deposit, and also for determining the efficiencies of oil shale retorting processes. For issues involving exchange or leasing agreements of public oil shale lands in the western United States, the Fischer assay is the only accepted method to determine the value of the lands in question.

Because the Fischer assay does not provide information about what chemical properties of oil shales are important for producing liquids, a number of studies have been made to correlate various chemical and physical property measurements with oil yields determined by the Fischer assay. Even the Fischer assay procedure has been

modified to assay different types of oil shale, or to resemble, more closely, a certain type of retorting process. Other reasons for the development of alternate assay methods are that the Fischer assay is fairly time-consuming and the desire to have on-line assaying methods at an oil shale retort.

A summary of some methods for correlating oil shale properties with Fischer assay oil yields is given in Table 2. In general, these methods attempt to measure a parameter that is associated with the quantity of organic matter in the sediment and do not take into account the quality of the organic matter, i.e. its chemical structure. As such, most of them are specific to a given oil shale formation. For example, a correlation derived for oil shales from the Green River Formation in Colorado in the United States is probably not valid for a different oil shale formation, such as, for example, oil shales from the Rundle Deposit in Queensland, Australia. A new correlation must be established for every new deposit.

2.1.2 Elemental Analyses

The elemental composition of an oil shale can be correlated with oil yields determined by the Fischer assay.\(^\text{(16,17)}\) The best correlation for Green River Formation shales is between organic carbon and Fischer assay oil yields. This is not surprising since organic carbon constitutes the major element in the composition of an oil shale. Cook\(^\text{(16)}\) obtained Equations (1) and (2) for oil yield based on weight percent (wt%) or gallons per ton:

\[
\text{Oil (wt\%) = 0.832 (\%orgC) - 0.251} \quad (1)
\]

\[
\text{Oil (gal ton}^{-1}\text{) = 2.22 (\%orgC) - 0.771} \quad (2)
\]

where \(\%\text{orgC}\) is the wt\% organic carbon. These correlations were obtained prior to the development of solid-state NMR techniques. However, it is of interest to note that the coefficient of 0.832 in Equation (1) is close to the fraction of aliphatic carbon (0.80) in Green River Formation oil shale determined by \(^{13}\text{C}\)-NMR measurements.\(^\text{13}\) The aliphatic carbon content for any oil shale has been shown to be a good indicator of oil yield.\(^\text{28,36–41}\)

For Devonian (Cleveland member) and Mississippian (Sunbury member) black shales from the eastern United States, organic carbon also correlates with Fischer assay oil yield (Figure 1).\(^\text{17}\) However, because of differences in maceral compositions (quality) of the organic matter in different deposits,\(^\text{42}\) the data are best fit with separate regressions for deposits from different geologic ages.

If the quality of the organic matter does not change significantly in the formation, then correlations based on organic carbon are applicable, and organic carbon content is a good indicator of the quantity of organic matter in the sediment. As a rule of thumb, the Fischer assay oil yields in gal ton\(^{-1}\) for Green River Formation oil shales are about 2–2.5 times \(\%\text{orgC}\). For Devonian oil shales from the eastern United States, the oil yields in gal ton\(^{-1}\) are about

equivalemt to %orgC. For the shales from eastern Kentucky (Figure 1), the Sunbury and Cleveland shales produce 1.03 and 1.18 gal of oil per unit %orgC, respectively.

2.1.3 Laser Pyrolysis

Laser pyrolysis chromatography has also been suggested as a method for analyzing oil shales. The method involves using a laser to rapidly pyrolyze the kerogen in an oil shale, followed by detection of the pyrolysis products by gas chromatography (GC). Because of the extremely high temperatures involved during the pyrolysis, acetylene is the major organic species in the product gas mixture. The amount of acetylene produced correlates with the oil yield. With a flame ionization detection (FID) probe only organic species are detected so that the integrated chromatogram is proportional to the amount of organic matter. Some disadvantages of the technique are that the oil shale must be ground, then pelletized before analysis. Because the laser is focused onto a small area, it is important that the pellets be uniform in oil shale composition so that the samples are representative of the deposit. Also, it is important that the amount of laser energy absorbed by the sample be the same for each laser pulse in order to achieve reproducibility.

2.1.4 Thermal Chromatography

A procedure for assaying oil shales based on thermal analytical methods has been suggested. This method is a low-temperature method compared with laser pyrolysis. In the thermal chromatographic method, an oil shale is heated (~30 °C min⁻¹) to a temperature of 600 °C. Hydrocarbon gases that are evolved during heating are measured with a gas chromatographic flame ionization detector. The total amount of evolved gases correlates with the Fischer assay oil yields. A disadvantage of this procedure is that small sample sizes (milligrams) must be used; therefore, sample homogeneity and particle sizes could present problems. An advantage is that the evolved gases can be analyzed by GC to obtain information about the organic matter just as in laser pyrolysis. These methods are similar to the Rock-Eval pyrolysis method used in geochemical analyses for determining kerogen type and maturity. Rock-Eval measurements have been shown to correlate with Fischer assay oil yields.

2.1.5 Microwave and Thermophysical Methods

Microwave radiation has been suggested as an alternative heating method for assaying Colorado oil shales. The dissipation of microwave energy has been shown to be a strong function of the richness of an oil shale. The loss tangent, which is an index of a material’s ability to absorb microwaves and which is also related to the dielectric constant of the material, increases nonlinearly as shale richness increases linearly.

Thermal conductivity, thermal diffusivity, dielectric constant, specific heat and sonic velocity measurements have been made as a function of oil shale richness. However, none of these measurements appears promising as a method for assaying oil shale. In some cases, the measurements are dominated by the mineralogy. In addition the correlations are nonlinear, as are the microwave correlations, which tends to detract from their usefulness as assay methods.

2.2 Nonthermal Methods

2.2.1 Density Measurements

A simple, but effective, correlation of a physical property measurement with oil yield is the relationship between density and oil yield. These correlations are based on the simple observation that the oil shales having a high organic content are less dense than oil shales having a low organic content. Thus, by measuring the density of an oil shale, one is essentially measuring the weight fraction of organic matter in an oil shale. The relationship between density and weight percent organic content has been derived by Smith and has the form shown in Equation (3)

\[ D_T = \frac{D_A D_B}{A(D_B - D_A) - D_A} \]  

where \( D_T \) is the absolute density of the oil shale; \( D_A \) is the average density of the organic fraction; \( D_B \) is the density of the inorganic fraction; and \( A \) is the weight fraction of the organic matter. Equation (3) is a general expression and is applicable to any oil shale deposit. For Green River Formation oil shales, \( D_A \) is about 1.07, and \( D_B \) is about 2.72 g cm⁻³. An expression relating oil yield in gal ton⁻¹ and density for Green River oil shale is shown in Equation (4)

\[ \text{Oil (gal ton}^{-1} \text{)} = 31.6D_T^2 - 206.0D_T + 326.6 \]  

Schultz and Bates have correlated oil yields with oil shale density for oil shales and beneficiated products from oil shales from Alabama, Indiana, Kentucky, Ohio, Michigan and Tennessee. Their correlation between oil yield and densities is shown in Equation (5)

\[ \text{Oil (gal ton}^{-1} \text{)} = 29.9D_T^2 - 173D_T + 250.3 \]  

For New Albany oil shales from Kentucky, oil yields have also been shown to correlate with specific gravity and sound velocity measurements. The latter is somewhat redundant because sound velocity depends on density.
The method relating density to organic content only works well if the mineral and organic components are fairly uniform throughout the deposit, and the percentage conversion of organic matter to oil is uniform. If not, these types of correlations must be developed for each oil shale deposit. These conditions apply to all correlations that measure some chemical or physical property that relates to the quantity, and not to the quality, of the organic matter.

2.2.2 Spectroscopic Methods

2.2.2.1 Fourier Transform Infrared

FTIR spectroscopic measurements have been applied to obtain information about the aliphatic components in oil shales.\(^{(28,29)}\) Spectra are recorded from 4000 to 400 cm\(^{-1}\) and corrections are applied for particle scattering and mineral interferences. The CH stretching bands between 3100 and 2750 cm\(^{-1}\) are used to obtain a measure of the aliphatic carbon contents, which are then correlated with the Fischer assay oil yields. The FTIR methods have not been widely accepted for studying oil shales. One reason is that, because of the small sample sizes used, obtaining a representative sample is a concern.

2.2.2.2 Electron Spin Resonance

Attempts have been made to correlate ESR measurements with oil yields.\(^{(30,31)}\) The assumption behind these measurements is that the organic free-radical concentration might correlate with oil yield. Stable organic free radicals are associated with aromatic components, whereas oil yield is more closely associated with the hydrogen-rich aliphatic components. Unfortunately unpaired electrons from the minerals also contribute to the ESR signal. Nevertheless, for a set of Colorado oil shales from the same core, the ESR signal gives a fair correlation with oil yields. However, in the case of eastern US oil shales, no correlation between ESR measurements and oil yield was found when samples from different locations were analyzed.\(^{(31)}\)

2.2.2.3 Proton (\(^{1}\)H) Nuclear Magnetic Resonance

It is reasonable to assume that the amount of hydrogen in an oil shale should be an indicator of the potential oil yield of an oil shale because the amount of available hydrogen is a key factor in producing liquids during pyrolysis. Consequently, correlations have been developed between hydrogen content and Fischer assay oil yields.\(^{(32–35)}\) These were based on the use of pulsed NMR methods, in which the signal amplitude measured immediately after a 90° pulse is directly proportional to the amount of hydrogen in the shale. A comparison of a Fischer assay oil yield histogram and a pulsed NMR hydrogen response histogram is shown in Figure 2. The NMR response, which is in arbitrary units, quite faithfully mimics the Fischer assay histogram. Some advantages of pulsed NMR methods are that they are rapid and nondestructive, and can be easily automated. They could be used for rapidly screening an oil shale deposit. Disadvantages are small sample sizes, and interferences due to protons in water and clay minerals. Also, because pulsed NMR provides a measurement of total hydrogen, and not just organic hydrogen, calibrations must be established for each oil shale deposit.

2.2.2.4 Carbon (\(^{13}\)C) Nuclear Magnetic Resonance

Except for the FTIR measurements, the assay methods described in the previous sections have one thing in

![Figure 2](image-url)
common. They all measure, or attempt to measure, some physico-chemical parameter associated with the amount (quantity) of organic matter in an oil shale. While these methods might provide reasonably good correlations with oil yields, they are generally only valid for a specific deposit, and only valid if the type of organic matter, or its composition, does not vary significantly throughout the deposit. None of the methods provides much insight into what chemical structures are important for producing shale liquids during pyrolysis of oil shales.

The importance of kerogen structure in the conversion behavior of oil shales has been known for a long time.\(^6\) However, it was only with the development of solid-state \(^{13}\)C-NMR techniques that direct information about the carbon structure could be obtained. An example of the importance of kerogen chemical structure for producing shale oil is illustrated by the \(^{13}\)C-NMR spectra shown in Figure 3. The total organic carbon is essentially the same for the three oil shales; however, the percentage of conversion of organic carbon to oil during Fischer assay retorting is different for the three shales. The CP/MAS solid-state \(^{13}\)C-NMR spectra show clear differences in the carbon distributions of the oil shales. Most of the organic carbon in the Colorado oil shale is in the form of aliphatic carbon structures (0–50 ppm), whereas a substantial portion of the organic carbon in the Kentucky oil shale is in aromatic carbon structures (100–150 ppm). The oil shale from Morocco has a carbon distribution in between. These data provide a quantitative basis for previous concepts that kerogens with a high H/C ratio (ca. 1.5 or more), so-called Type I kerogens, produce greater quantities of oil during maturation than do Type III kerogens which have an H/C ratio less than unity.\(^2\)

By combining the NMR measurements of aliphatic carbon ratios of the kerogen, with organic carbon contents of kerogen, good correlations have been obtained that are independent of depositional environment, geographic location or geologic age.\(^{28,36–41}\) In Figure 4, correlations are shown between Fischer assay oil yields and total organic carbon and aliphatic carbon for 55 oil shales from different deposits around the world. The data clearly show that chemical structure, i.e. aliphatic carbon, is important for producing shale oils during retorting.
The effects of kerogen chemical structure on the conversion behavior of oil shales can be studied by combining solid- and liquid-state NMR measurements with material balance Fischer assay data. In a material balance Fischer assay the elemental composition is determined for the raw shale and the gas, oil and spent shale products. The elemental composition of the gas is calculated from the gas composition which is determined by GC. The assay data can be normalized to the basis of 100 carbon atoms, from which the percentage of carbon in the different products can be calculated. The percentage of organic carbon in the raw shale can be used as an indicator of the quantity of organic matter (kerogen) in raw shale. From these combined measurements, insight into some of the chemistry of kerogen decomposition can be obtained. A knowledge of the chemistry of kerogen decomposition could lead to more efficient retorting processes.

In this section, the effects of carbon structure on the conversion behavior of several oil shales are described for a set of ten oil shales from different deposits around the world. Material balance Fischer assay data are given in Table 3, and normalized NMR conversion data are given in Table 4. During pyrolysis, there is an increase in the amount of aromatic carbons in the products (oil plus residue) over that in the original shale. This increase is produced at the expense of aliphatic carbon moieties, which produce aromatic carbon by dehydrogenation of hydroaromatic structures and by ring closure of alkyl groups followed by dehydrogenation. The combined use of solid- and liquid-state $^{13}$C-NMR, in conjunction with the material balance Fischer assay conversion data, allows some inferences to be made about the extent of aromatization reactions during heating. The Alaska shale has the greatest loss of aliphatic carbons to aromatization reactions (Table 4).

* Ratio of residue aliphatic carbon to raw shale aliphatic carbon.
and Turkey shales also show substantial losses of aliphatic carbons to aromatization reactions. When expressed as a percentage of the raw shale aliphatic carbons, a more realistic comparison of the importance of aromatization reactions for the shales is obtained (Table 4). The Kentucky, Morocco and Turkey–Seyitömer oil shales show the greatest percentage decrease in aliphatic carbons. These shales also show the lowest carbon conversions to oil and the highest carbon conversions to residue.

The implication of these observations is that coking (aromatization) reactions are more prevalent in the Kentucky, Morocco and Turkey–Seyitömer shales. However, it cannot always be established to what extent these reactions occur in the solid or liquid state. For the Alaska shale the net effect of the aromatization reactions is to produce oil, because the number of aromatic carbons (16) in the raw shale is not sufficient to account for the number of aromatic carbons (25) in the oil. For the remaining shales, the number of aromatic carbons in the shale oil is substantially less than the number of aromatic carbons in the raw shale. Consequently, the origin of the aromatic carbons in the shale oil is not conclusive. In the case of the Kentucky shale, the number of aromatic carbons (49) in the raw shale is not sufficient to account for the number of aromatic carbons (56) in the residue. Therefore, at least seven of the raw shale aliphatic carbons are converted to aromatic carbons in the residue. This assumes that coking of the shale oil vapor does not occur during Fischer assay.

A plot of the ratio of the number of aromatic carbons in the residue versus the number of aromatic carbons in the raw shale is shown in Figure 5. If this ratio is greater than unity, then the minimum number of aliphatic carbons that have aromatized to form residue can be determined. If the ratio is less than unity, the source of the residue aromatic carbons cannot be determined. Figure 5 shows that the Australia, Kentucky and Turkey–Seyitömer oil shales have ratios greater than unity, suggesting that the aromatization reactions to form coke are most prominent in these shales. The Morocco, China–Maoming and Turkey–Göynük shales have ratios close to unity (>0.93). Except for the Turkey–Göynük shale, all of the shales with ratios greater than or near unity show the lowest aliphatic carbon conversions to oil during Fischer assay. The data in Figure 5 suggest that the shales can be divided into three groups with regard to coking tendency, based on the ratio of residue aromatic carbon to raw shale aromatic carbon. Thus, the coking tendency is Australia, Kentucky, Turkey–Seyitömer > China–Maoming, Morocco, Turkey–Göynük > Alaska, Brazil, China–Fushun, Colorado.

Some of the aliphatic carbons in the kerogen end up as aliphatic carbons in the residue. Although these carbons are not involved in coking reactions, they represent a loss in oil potential. These carbons are most likely short-chain (methyl, ethyl) aliphatic carbons attached to aromatic rings. Figure 6 shows the aliphatic carbon content of the residue, expressed as a percentage of the raw shale aliphatic carbon. The interesting feature of these data is that this percentage is in the 10–20% range for most of the shales, independent of kerogen structure and conversion behavior.

![Figure 5](image-url)  
4 SHALE OIL ANALYSIS

4.1 Introduction

The physical properties and the chemical compositions of shale oil depend on the source of the raw shale and the type of process used to obtain the oil. Shale oil can be obtained from oil shales by in situ and ex situ (surface) retorting. Laboratory quantities of shale oil for comparative studies and analytical methodology development are often obtained by the Fischer assay method. Chemical analyses of shale oils produced by various retort methods have been used to compare oil shale properties from different locations and with depth of the deposit and to monitor and/or determine optimum retorting parameters. Basically, shale oils differ from petroleum primarily in that they have a higher nitrogen content, and because shale oils are produced by pyrolysis, they contain higher concentrations of olefins, which are generally found in natural crude oils in low concentrations, if at all. Because of these materials, shale oils are relatively thermally unstable, have poor long-term storage stability, and require modifications of the analytical methods used for petroleum characterization.

4.2 Separation Methods

Shale oils as well as other fossil fuels are complex mixtures of hydrocarbons and heteronuclear molecules. Thus, it is necessary to separate them into fractions in order to obtain information on molecular types and to identify individual compounds. The separation techniques most often used are distillation, simulated distillation, and various forms of chromatography – gas, liquid, ion-exchange chromatography (IEC), size-exclusion chromatography (SEC) and high-performance liquid chromatography (HPLC). In addition, shale oils often contain substantial amounts of water that interfere with fractionation of the oil using the various separation techniques and subsequent analyses. Generally, water is removed by distillation using a standard ASTM method.

The elemental composition of the dried oil is determined using commercially available standard combustion instrumentation. Oxygen content is usually obtained by difference. Heating value of the shale oils can be computed from the elemental analysis data and the Boie equation (Equation 6).

$$H = 8400(C) + 27765(H) + 1500(N) + 2500(S) - 2650(O)$$

where H is the gross heating value in cal g⁻¹, and C, H, N, S and O are the normalized weight fractions of these elements in the shale oil. Other properties such as specific gravity, viscosity and pour point are also determined on the raw shale oil using standard ASTM procedures. Table 5 lists the elemental composition, carbon and hydrogen aromaticity values, molecular weights and specific gravity for Fischer assay shale oils from different oil shale locations worldwide.

4.2.1 Distillation Techniques

4.2.1.1 Hempel Distillation Much of the early work on the characterization of shale oil used the Hempel distillation method\(^{62}\) to obtain shale oil fractions having boiling point ranges similar to petroleum fractions obtained by distillation. In this method the crude shale oil is distilled into 14 subfractions, each having a boiling range of 25°C. The first seven subfractions are collected at 760 mmHg (25–200°C) and the remaining seven subfractions at 40 mmHg (200–350°C). Specific gravity is measured on all subfractions, including the residue, and the viscosity is measured on fractions 11–14. The residue is analyzed for carbon residue and ash content to give an indication of carbon particulates and mineral matter in the oil.\(^{50,51}\) Subfractions 1–7 are combined to give the naphtha fraction (25–200°C), subfractions 8–10 to give the light distillate fractions (106–200°C at 40 mmHg), and subfractions 11–14 to give the heavy distillate fraction (200–300°C at 40 mmHg).

Naphtha Fraction. Figure 7 is a schematic diagram of the procedure used to separate further the shale oil naphtha fraction into numerous fractions using an efficient fractionating column for the identification of the compound types and individual compounds.\(^{55,63}\) Naphtha distillates from crude shale oils produced by several methods of retorting Colorado oil shale were analyzed and found to be remarkably similar. The results indicate that the approximate composition of raw shale oil naphtha is: paraffins and naphthenes 30%; olefins 40%; aromatics 20%; sulfur, nitrogen and oxygen compounds 10%. Paraffins and aliphatic olefins, which comprise about two-thirds of their respective groups, are predominantly straight-chain compounds. The sulfur, nitrogen and oxygen are present principally in the form of thiophenes, pyridines and phenols, respectively.

Light Distillate Fraction. The shale oil distillate fraction that has received the least attention is the light distillate. This is the fraction that boils between 106 and 200°C at 40 mmHg (equivalent to the 200–300°C range if it were obtained at 760 mmHg). Analysis of the neutral oil obtained from the light distillate fraction\(^{64}\) showed the paraffins and naphthenes content to be 10%, olefins 29% and aromatics 61%. The percentages of tar acids and bases were not determined.

Heavy Distillate Fraction. A series of separation techniques, outlined in Figure 8, has been applied to the heavy distillate from Colorado shale oil.\(^{65}\) The techniques used were adsorption employing several different absorbents, vacuum distillation, thermal diffusion and complex formation. The hydrocarbon content made up approximately half of the heavy distillate (57%). Concentrates obtained from the heavy distillate were those composed of nitrogen compounds (43%) and aromatic, saturated and olefinic hydrocarbons (57%). The concentrates containing the saturates and olefinic materials (35%) were further subdivided into straight- and branched-chain compounds, and the aromatic concentrate (22%) was subdivided into fractions containing different numbers of condensed aromatic rings. For the nitrogen concentrate, separation was made into fractions containing different relative percentages of basic and nonbasic nitrogen.

4.2.1.2 Simulated Distillation Simulated distillation technique is a temperature-programmed gas–liquid chromatographic procedure for determining the distillation profiles of crude oils.\(^{66}\) The chromatographic data are divided into desired distillate fractions from correlations between GC retention times and normal alkane boiling points. The concentration (wt%) of each distillate fraction is determined using response factors obtained from standard samples. The results
are reported as concentration (wt%) of distillable material versus temperature.\(^{67}\) The boiling ranges of the fractions are chosen to correspond to the true boiling point distillation range of typical crude oil fractions.

The simulated distillation properties of the different Fischer assay shale oils\(^{45}\) from different oil shales worldwide are given in Table 6. The amount of distillate in each of the fractions does not differ significantly among any of the shale oils, except for possibly the residue. The bulk of the oil (>50%) distills in two boiling ranges, the atmospheric and vacuum gas oil fractions. The temperature at which 50% of the shale oil has distilled off is shown in Figure 9. The average 50% off temperature for all the shale oils is 369 ± 16 °C (95% confidence). This temperature is close to the average temperature of petroleum crude atmospheric gas oil fractions, which is 374 °C.

### 4.2.2 Chromatographic Techniques

Shale oil and shale oil fractions are extremely complex mixtures and while individual identification of the major components is conceptually and technically possible, the task is exceedingly time-consuming. Thus, characterization of a shale oil or fraction thereof in terms of molecular class (saturates, olefins and aromatics) and average molecular properties of a particular shale oil or fraction is an alternative approach to individual compound identification. There are many chromatographic and extraction techniques which can be used to separate oil into chemical classes of organic compounds.

Adsorption displacement chromatography can be used to separate the shale oil distillates in the 200–325 °C boiling range into saturates, olefins and aromatic fractions.\(^{68}\) Later papers\(^{65,69}\) describe the methodology to separate a high-boiling shale oil distillate (gas oil) into...
two concentrates using Florisil as an adsorbent (Figure 8). One concentrate contains most of the nitrogen compounds originally present in the distillate, and the other contains predominantly hydrocarbons. The hydrocarbon concentrate is then further separated into concentrates of aromatics, olefinic and saturated compounds by a two-step process, employing silica gel as the adsorbent. The aromatics are first removed from the saturates and olefins. These latter compounds are then separated from each other, using a much higher adsorbent/sample ratio than is used to remove the aromatics. Further separations of these concentrates are made by vacuum

distillation, thermal diffusion, adduct formation or additional adsorption techniques.

Elution chromatography can be used to separate shale oils into various fractions. Typically, the column is packed with two-thirds silica gel topped with one-third alumina. The linear aliphatic and alicyclic hydrocarbon fraction is first eluted using a light petroleum followed by dichloromethane to elute the aromatic hydrocarbons and thio-aromatics. Methanol is used last to elute the polar nitrogen, sulfur and oxygen fractions. Separation of the aliphatic/alicyclic hydrocarbon fraction into saturates and unsaturates (olefins) is achieved by thin-layer chromatography (TLC) using plates coated with 0.5-mm thick silica gel and containing 10% silver nitrate. Branched and cyclic hydrocarbon fractions are separated from saturated fractions by urea addition. Oil shales from different locations can be compared using the weight percents calculated for the various fractions.

Hydrogen types and polar materials, including acids and bases in shale oil distillates, can be determined using a combined subtraction and gas chromatographic technique. This method consists of adding an appropriate internal standard to the sample, applying a specific subtraction technique and determining the amount of a compound type from comparison of the before and after gas chromatograms. The precision and detection limits are set by the precision of the gas chromatographic readout at about ±1%. The subtraction technique with GC readout is not useful for trace analyses. However, the data for compound types present in shale oil at the level of a few per cent allow use of the method for more detailed characterization of polar materials.

Brown et al. using gas-liquid chromatographic separation and spectrometric techniques, have identified 50 individual compounds in the nitrogen base fraction obtained from a hydrocracked shale oil naphtha fraction. They found that alkylpyridines comprised about 64% of the bases and alkylanilines about 33%. The rest of the bases were quinoline and small quantities of cycloalkanopyridines.

Preparative liquid chromatography and glass capillary GC were used to separate shale oil hydrocarbons into fractions of alkanes, alkenes and aromatics. In addition, resolution of individual components of branched and cyclic alkanes and alkenes was achieved using a vapor-phase subtraction technique employing 100–200 mesh molecular sieve 5A. A chemically bonded pyrrolidone substrate was used for the HPLC to separate polycyclic aromatic hydrocarbons (PAH) according to the number of aromatic rings and the type of ring condensation.

### 4.3 Spectroscopic Methods for Shale Oil Analyses

One of the first reported uses of instrumental methods of analysis for crude shale oil fractions was by Ball et al. Using ultraviolet (UV) absorption spectroscopy these authors qualitatively identified numerous aromatic compounds in the naphtha fraction obtained from the distillation of crude shale oil. Dinneen et al. used the technique to investigate high-boiling shale oil distillate. UV spectroscopy was also used in the investigation of the types of sulfur and nitrogen compounds in shale oil.

Infrared (IR) spectroscopy was first applied in 1952 to the identification of tar acids isolated from shale oil and later was used to confirm the straight-chain character of the urea–hydrocarbon adduct for saturated and olefinic fractions. In 1956 Cook and Church used IR spectroscopy to study the pyridine compounds isolated from shale oil tar base fractions. In succeeding years, other nitrogen-type compounds in shale oil also were identified by IR spectroscopy. Olefin types found in shale oil were characterized by IR spectroscopy as early as 1960 and later by Jackson et al. The polar constituents as well as normal and isoprenoid hydrocarbons isolated from oil shale bitumen and kerogen were studied by Robinson and co-workers.

Mass spectrometry (MS) has been used extensively as an analytical tool in the petroleum industry. Thus, it is not surprising that MS has also been applied to shale oils. MS, as an analytical tool, was used by Van Meter et al. to evaluate the Dumas procedure for determining the nitrogen content in shale oils. The first reported use of MS for the identification of hydrocarbons in shale oil was in 1952 by Dinneen et al. A more extensive use of MS for the characterization of saturates and olefins in shale oil was reported by Jensen et al. Normal, isoprenoid and alicyclic hydrocarbons, fatty acids and other polar...
constituents,\(^{(89,94)}\) steranes\(^{(95)}\) and substituted tetralins in oil shale bitumens also have been identified using MS. Using the combined techniques of gas chromatography/mass spectrometry (GC/MS), Morandi and Guffey\(^{(96)}\) identified isoprenoids, steranes and terpanes in a Fischer assay shale oil. Ciccoli et al.\(^{(97)}\) used the GC/MS technique to study New Albany Shale, and Jones et al.\(^{(98)}\) also characterized shale oils and related fuels using the technique.

The application of MS to the analysis of olefins and mixtures of olefins is extremely difficult. However, since shale oil can contain as much as 30% olefinic materials, several studies directed toward the identification of olefins using MS were conducted based upon deuterium labeling\(^{(99,100)}\) and derivatization\(^{(85)}\) techniques. Earlier MS studies reported direct identification of aliphatic olefins\(^{(63)}\) and diolefins.\(^{(84)}\)

Morandi and Jensen\(^{(76,101)}\) used the mass spectral technique to identify porphyrins in shale oil and oil shale. Other nitrogen compounds were also identified using MS in the raw, refined shale oils,\(^{(56,61,77)}\) shale oil naphtha\(^{(71)}\) and gas oil fractions.\(^{(69)}\) Not only were the nitrogen compounds identified in shale oil by MS, but the sulfur compounds were also identified.\(^{(102,103)}\) A compilation of mass spectra of organic sulfur compounds was published by Cook and Dinneen.\(^{(104)}\)

Less common analytical techniques were also used to investigate shale oils. Fluorescence spectrometry was used by Hurtubise et al.,\(^{(105,106)}\) to characterize and identify polynuclear aromatic hydrocarbons in shale oil, and the first systematic study of the free-radical content in raw shale, shale oil and spent shale using electron paramagnetic resonance spectroscopy was reported by Sidwell et al.\(^{(50)}\)

\(^1\)H-NMR techniques have been used extensively to rapidly characterize hydrocarbon types in petroleum. The first reported use of \(^1\)H-NMR to study oil shale bitumen was in 1964 by Cummins and Robinson.\(^{(86)}\) They used the technique to confirm the methyl branching characteristics of isoprenoid compounds. \(^1\)H-NMR was also used to confirm the identity of both isoprenoid compounds and a number of polar constituents isolated from Green River oil shale. The \(^1\)H-NMR characterization of saturates and olefins in shale oil was conducted by Jensen et al.,\(^{(91)}\) and Jackson et al.\(^{(85)}\) Several papers were published on the use of \(^1\)H-NMR to identify nitrogen compounds in shale oil.\(^{(71,77)}\)

As in the case of \(^1\)H-NMR, \(^{13}\)C-NMR was first applied to petroleum crude oil investigations and coal liquid fractions. NMR has been used to characterize hydrocarbons in shale oil\(^{(107)}\) and to study oil shale in the solid state.\(^{(57)}\) Netzel et al.\(^{(108)}\) have used both \(^1\)H- and \(^{13}\)C-NMR to study the naphtha and light distillate saturated hydrocarbon fraction obtained from in situ shale oil. Both solid-state and high-resolution \(^1\)H- and \(^{13}\)C-NMR have been used to compare the hydrocarbon composition of shale oils produced by the pyrolysis and hydropyrolysis of Eastern and Western US oil shales.\(^{(109)}\)

5 ANALYTICAL APPLICATION OF HIGH-RESOLUTION NUCLEAR MAGNETIC RESONANCE TO THE STUDY OF SHALE OIL FRACTIONS

NMR spectroscopy is an extremely useful technique for structural characterization of organic compounds and for quantitation of major functional groups in complex mixtures. The advantages of NMR spectroscopy are that it is nondestructive and the spectroscopic data can be reduced relatively easily to give the desired information. The technique is not as sensitive as MS and the application of the NMR to a mixture of similar organic compounds gives only the average structural properties of the molecular composition. As a result, the method is most useful for fractions in a narrow boiling range.

The chemical changes that occur when an oil shale is subjected to various physical and chemical treatments to yield shale oil can be followed using both liquid and solid-state NMR. Figure 10 shows the solid-state CP/MAS \(^{13}\)C-NMR spectrum of a typical Colorado oil shale, and the spectra after the oil shale was (1) treated thermally to yield raw shale oil, (2) extracted with benzene before heating to yield shale oil bitumen, and (3) acid-treated to yield kerogen concentrate. One parameter which can easily be determined from each spectrum is the carbon

\[ \text{Figure 10} \] 
\[ \text{\(^{13}\)C-NMR spectra of Colorado oil shale, kerogen, bitumen and shale oil.} \]
aromaticity, $f_a$. This parameter is the fraction of aromatic carbons (aromatic integrated area) divided by the total number of carbons (sum of the aromatic and aliphatic integrated areas) measured in the NMR spectrum. The aromaticity values for this oil shale, shale oil, kerogen concentrate and bitumen were found to be 0.30, 0.295, 0.23 and 0.14, respectively.

To obtain additional average molecular structural information on the shale oil by NMR, the Hempel distillation method can be used to fractionate shale oil into naphtha, light distillate, heavy distillate and residue fractions. Figure 11 shows the high-resolution $^{13}$C-NMR spectra for the different fractions from a Hempel distillation of an oil shale. Not only can the aromaticity value be measured for each fraction, but also other details about the average aliphatic structure can be obtained. These include the average carbon chain length of the alkane and relative percentages of normal and branched–cyclic alkanes. The naphtha and light distillate fractions can be further subdivided into saturates, olefins and aromatic subfractions by silica gel chromatography. A discussion of the NMR spectra of these subfractions follows.

### 5.1 Saturates

The $^1$H-NMR spectra of the saturates from the naphtha and light distillate fractions of shale oil are shown in Figures 12(a) and 12(b), respectively. The resonance signals observed in the aliphatic region of the spectra are due to normal, branched and cyclic alkanes. Spectral assignments of the alkane hydrogens and the quantitative information which can be obtained have been discussed in the literature.\(^{110–112}\) Table 7 lists the $^1$H-NMR chemical shift values for the different hydrogen types. The interpretation of the $^1$H-NMR spectra is straightforward. The resonance signals ranging from 0.5 to 1.0 ppm are due to terminal and branched methyl hydrogens. Methylene hydrogens in straight-chain or branched hydrocarbons have resonances in the range 1.2–1.3 ppm. The signal at 1.27 ppm in each spectrum is thus assigned to the methylene hydrogens. The intensity of this signal is primarily indicative of the alkane chain length. Cyclic methylene hydrogens range from 1.1 to 1.8 ppm. The shoulder at 1.34 ppm on the left of the straight-chain methylene hydrogens is assigned, in part, to these hydrogen types. Because of the overlap of the resonance signals of cyclic

![Figure 11](image-url)
and straight-chain methylene hydrogens, the amount of quantitative information which can be extracted from these spectra is limited. However, area ratios of the methylene to methyl hydrogens were found to be 2.1 and 2.5 for the naphtha and light distillate saturates, respectively. Thus, semiquantitatively the naphtha saturates have on average shorter alkane chain lengths than the light distillate saturates. No evidence for aromatic (6–9 ppm) or olefinic (4–6 ppm) hydrogens can be found, indicating that the silica gel separation method is quite satisfactory for separating the saturates of the naphtha and light distillate fractions from other hydrogen types.

Figures 13(a) and 13(b) are 13C-NMR spectra of the aliphatic region for the saturate cuts from the naphtha and light distillate fractions, respectively. The relatively few resonances shown in each spectrum suggest that the major constituent carbon types can be identified and quantified. The 13C-NMR chemical shifts for the different carbon types are listed in Table 7. The following discussion refers to the 13C-NMR spectrum of the light distillate saturate fraction (Figure 13b) but is also applicable to the interpretation of the 13C-NMR spectrum of the naphtha saturate fraction. The five intense lines at 14.18, 22.88, 32.16, 29.62 and 29.95 ppm relative to TMS correspond to C-1, C-2, C-3, C-4 and C-5, respectively, of long-chain normal alkanes (see Figure 13b). However, neither the chemical shifts nor intensities correspond to any one \( n \)-alkane, since the spectrum is a composite of a distribution of several long-chain normal alkanes. The next set of resonances of medium intensity in the 13C-NMR spectrum is due to symmetrically branched linear hydrocarbons having an isoprenoid-like structure. Phytane, pristane and others have all been identified in oil shale.\(^{113}\) Figure 14(a) shows the identification of the signals with the corresponding carbon atoms in farnesane, a \( C_{15} \) isoprenoid.\(^{114}\) The remaining signals in the 13C-NMR spectrum of the light distillate saturates are due to unsymmetrically branched alkanes and cyclic alkanes. Some representative structures are shown in Figure 14(b).

The relative percentage of the combined branched and cyclic alkanes can be calculated by subtracting the area due to the \( n \)-alkanes from the total 13C-NMR aliphatic carbon area. The ratio of the area of the branched and

5.2 Olefins

$^1$H-NMR can be used to analyze olefins in shale oil fractions. The proton spectra of the olefins obtained from cyclic alkane carbons to the total aliphatic carbon area for the light distillate saturate fraction was found to be 0.31. Analytical results from a GC/MS determination on the same sample gave 73% $n$-alkanes, 20% branched alkanes, and 7% unidentified. The sum of the branched alkane and unidentified species content determined by GC/MS (27%) agrees reasonably well with the value found by $^{13}$C-NMR (31%). A comparison of the MS and NMR percentage compositions for the saturate cuts from the naphtha and light distillate fractions is listed in Table 8. The data show that the NMR analysis of the saturates can give results comparable to GC/MS analysis.

the naphtha and light distillate fractions (Figures 15a and 15b respectively) show the presence of large amounts of methyl and methylene hydrogens and the presence of olefinic hydrogens at about 5.38 ppm relative to TMS. The $^1$H-NMR olefinic region from 4 to 6 ppm has essentially no interference from hydrogens of other
types of functional groups. Thus, the olefin content can be measured quantitatively even for fractions with low olefin content. However, the position of the double bond in the alkene molecules cannot always be ascertained from the $^1H$-NMR spectra but can from $^{13}C$-NMR spectra.

The $^{13}C$-NMR spectra (Figures 16a and 16b) of the olefin fractions of the shale oil naphtha and light distillation cuts can show clearly the position of the double bond for the different olefins. For the 1-ene olefin the carbons associated with the double bond are at 114 and 138 ppm. As the double bond moves along the carbon chain the differences between the chemical shifts of the two carbon atoms get smaller. For the 5-ene olefin, the carbon atoms associated with the double bond have nearly the same chemical shift. Thus, within the olefinic carbon region (114–138 ppm), it is possible to identify the most dominant double bond positions and determine their corresponding relative percentages. Table 9 lists the positions of the dominant olefinic bonds identified in the olefin subfractions of the naphtha and light distillate fractions. Also included in Table 9 are the observed chemical shifts of the olefinic carbons and the relative percentages. The double bond positions were identified by comparing the observed chemical shifts with those reported by Couperus et al.$^{115}$

5.3 Aromatics

The $^1H$-NMR spectra of the aromatic naphtha and aromatic light distillate fractions show considerable detail as to the types of protons present. In the naphtha fraction (Figure 17a), the $^1H$-NMR spectrum shows evidence for the existence of small amounts of di- and triaromatic ring molecules (peaks with $^1H$-NMR chemical shift values greater than 7.2 ppm). There is no evidence of these molecules in the light distillate fraction (Figure 17b) at the recorded signal-to-noise level. The relative amount of aromatic protons is also less in the light distillate than in the naphtha fraction (8.7% and 23.8%, respectively). In addition, the naphtha fraction has more $\alpha$-CH$_2$ (42%) (CH$_2$ groups attached directly to an aromatic ring) than the light distillate fraction (26.6%). Thus, the $^1H$-NMR data suggest the naphtha fraction contains mostly substituted monoaromatic compounds with apparently small amounts of di- and triaromatic molecules. The light distillate fraction is, on the other hand, composed mostly of monoaromatics which are less substituted, but the alkyl substituent is of longer carbon chain length.

Figure 18: 

![13C-NMR spectra](a) (b) 

The \(^{13}\)C-NMR spectra of the aromatics for both the naphtha and light distillate fraction (Figures 18a and 18b, respectively) show a large number of narrow and distinct resonances which, in principle, can be interpreted as to specific carbon type present. The naphtha fraction contains more aromatic carbons (greater aromaticity) relative to the light distillate fraction (54% and 32%, respectively). The corresponding relative amounts of
aliphatic carbons were found to be 46% and 68% for the naphtha and light distillate fractions respectively.

A number of average molecular structural parameters\(^{(116)}\) can be calculated for the aromatic subfraction of an oil. The underlying assumption is that the aliphatic carbons are attached to the aromatic molecule. Table 10 lists the definitions and equations for the structural parameters as well as the calculated values for the aromatic subfractions obtained from the naphtha and light distillate fractions from the Colorado shale oil. The data indicate that the average number of aromatic carbons per molecule in the naphtha fraction is 8.5 as compared with 5.3 in the light distillate fraction. The average numbers of saturate carbons per molecule are 7.2 and 11.5 and the average numbers of substituents per molecule are found to be 4.0 and 3.3 for the naphtha and light distillate fraction, respectively. The average carbon chain length per substituent for the naphtha and light distillate fractions is 1.8 and 3.4, respectively. From this information and additional data in Table 10, it appears that the naphtha fraction is highly substituted with short alkyl groups. The light distillate aromatic fraction on the other hand appears to have fewer substituents but longer carbon chain lengths per substituent. These conclusions are the same as the conclusions made from the \(^1\)H-NMR spectra.

### 6 CONCLUSION

In 1973 there was a false belief that the world supply of petroleum was being rapidly depleted and by the year 2000 petroleum crude would be completely depleted. At this time a major emphasis was placed on the commercialization of oil shale conversion from which gasoline, diesel and jet fuels can readily be produced. Extensive research was conducted to develop more cost-effective retorting processes and analytical methodology to evaluate oil shale processes and shale oil products. However, since the early 1980s the petroleum supply has increased and the development of an oil shale industry has been limited by the commercial reality that petroleum

can be produced less expensively than shale oil. Until that time when petroleum becomes unavailable or too expensive, there will be little or no incentive to produce synthetic liquid fuels from oil shale on a large scale. How far into the future this will continue is difficult to predict.

Utilization of oil shale to replace petroleum will mean searching for economically efficient and environmentally acceptable recovery processes for the energy-rich organic material locked inside the oil shale’s rock matrix. The recovery processes will involve a number of different kinds of technologies, including mining, size reduction, retorting or other means of recovering shale oil from the rock, disposal of the spent shale in an environmentally acceptable manner, and upgrading the shale oil into marketable products. On a commercial scale, to satisfy even a portion of the daily consumption of transportation fuels in the US, the amount of material that has to be mined and disposed of is staggering.

Because oil shales are diverse in their compositions, lithologies and genesis, their behavior during heating will also be different, as has been shown in preceding sections. Ongoing research continues at a low level. However, this has not led to new analytical methods to analyze oil shale and shale oil, so methods described in this article continue to be utilized.

Oxygenate Vapor–Liquid Equilibrium in Gasolines

Stanley I. Sandler
University of Delaware, Newark, USA
Kenneth N. Marsh
University of Canterbury, Christchurch, New Zealand

1 INTRODUCTION

The development of “clean gasolines” in the United States has resulted in considerable interest in the measurement and correlation of VLE data for oxygenate–hydrocarbon mixtures. Of primary interest are ethers and alcohols and the effect of such added oxygenates on the volatility of gasolines. Gasoline volatility is generally reported as the Reid vapor pressure, that is, the pressure that would be produced when the gasoline is placed in an evacuated, closed container and partially vaporized as described by the American Society for Testing and Materials (ASTM) standard ASTM-D 323-94 Vapor Pressure of Petroleum Products (Reid Method). The Reid vapor pressure is an important characterizing parameter for gasoline, and there are United States Environmental Protection Agency (USEPA) limits on its value in commerce.

Ethers and alcohols are being added to hydrocarbon fuels to produce the current generation of “clean gasolines” which are claimed to reduce air pollution. Also, alcohols provide a renewable energy source. However, the addition of oxygenates can change the volatility (as measured by the Reid vapor pressure) of a hydrocarbon mixture. This article reviews the equipment and measurement methods commonly used to study the vapor–liquid equilibrium (VLE) of hydrocarbon–oxygenate and gasoline–oxygenate mixtures. Detailed tables present those oxygenate–hydrocarbon mixtures for which VLE data are available.
processing and for end-use in the clean gasolines is VLE, although other data such as liquid–liquid equilibrium (LLE) data are also of interest, especially because of the possibility of liquid–liquid phase splitting in the presence of water, or at high alcohol concentrations.

3 METHODS USED

There are two parts to determining the VLE of oxygenate–gasoline systems: one is producing VLE in the mixture, and the other is determining the composition of the equilibrium phases (although, as described below, in some experimental techniques the composition of one of the phases is gravimetrically prepared).

There are a number of ways that VLE data for mixtures can be obtained. The most complete data set includes the pressure (P), temperature (T), and the mole fraction compositions of the co-existing liquid (x) and vapor (y). Such data are referred to as \( P-T-x-y \) data. For the correlation of such VLE data (especially for binary mixtures) it is preferable to have approximately 10 VLE points at each temperature covering the whole liquid composition range, together with the pure component vapor pressures measured in the same equipment. Usually, data for more than one isotherm would be reported. Data are also reported for a variety of compositions at a fixed pressure and therefore varying temperature. Such data are somewhat more difficult to correlate with thermodynamic models because of the temperature dependence of the model parameters, but are useful for distillation column design (as such devices operate close to isobarically), and generally are easier to measure using automated pressure control devices.

Other types of VLE measurements include ebulliometry, static cell devices, gas–liquid chromatography (GLC), and headspace chromatography. As will be discussed below, each of these provides useful, but less complete, data in that either only a limited range of compositions are measured, or the compositions of one of the phases are not measured.

Recirculation equipment for VLE measurements has been discussed previously.\(^1\)\(^-\)\(^2\) A double-recirculation still, one type of which is shown schematically in Figure 1, is frequently used to obtain \( P-T-x-y \) data. [Note: there are many variations of this type of still, as can be seen in the literature.\(^1\)\(^-\)\(^2\)] In the still shown, the liquid mixture boils in the still pot, producing a vapor–liquid mixture that is trapped in the inverted funnel region of a helical tube (a Cottrell pump), forcing the mixture into an adiabatic region where VLE is achieved. As the flow continues, the vapor and liquid phases disengage, the vapor is condensed, and the liquid and condensed vapor return to the still pot by separate lines. Samples for analysis may be removed from the liquids in each of these lines. Depending on the mixture under study, different analytical methods can be used. For binary mixtures, techniques such as gas chromatography (GC) with an appropriate detector (see Hyphenated Gas Chromatography, Column Technology in Gas Chromatography, Trace Organic Analysis by Gas Chromatography with Selective Detectors), refractometry (for binary mixtures that are liquids under ambient conditions) and densimetry, have been used. For composition measurements involving real and simulated gasolines, which are multicomponent mixtures, GC is most commonly used.

The advantage of complete \( P-T-x-y \) data for binary mixtures is that such data can be tested for thermodynamic consistency. However, such tests are not unambiguous. Also, composition measurements, especially of the condensed vapor, are the least accurate of the measurements made in VLE, and for some applications it is not necessary to have such complete data. Ebulliometry is one example of an experimental technique that results in useful, but less complete, data. In this technique, a gravimetrically prepared liquid sample is boiled in a still that recirculates the condensed liquid, and the temperature and pressure are measured. Figure 2 shows one example of such a device, though many variations exist. If the amount of recirculating liquid is not too large.

![Figure 1 Schematic diagram of a double-recirculation VLE still](image-url)
technique is generally limited to relative volatilities is known accurately. Consequently, this measurement of the equilibrium condensed vapor, neither of which of the amount of vapor holdup and the composition iterative procedure; however, this requires knowledge procedure is to correct for the liquid holdup using an and equilibrium compositions are identical. A common there is greater error in the assumption that the prepared amount of condensed vapor holdup in the still increases, in vaporization and loss of the more volatile component. as the prepared liquid), one then obtains \( P-T-x \) data, but not the composition of the co-existing vapor. Usually in such measurements, the pressure is fixed and the equilibrium temperature measured, since attempting to adjust the pressure might result in vaporization and loss of the more volatile component.

As the relative volatility of the components and/or the amount of condensed vapor holdup in the still increases, there is greater error in the assumption that the prepared and equilibrium compositions are identical. A common procedure is to correct for the liquid holdup using an iterative procedure; however, this requires knowledge of the amount of vapor holdup and the composition of the equilibrium condensed vapor, neither of which is known accurately. Consequently, this measurement technique is generally limited to relative volatilities

(Equation 1):

\[
\alpha_{ij} = \frac{y_i/x_i}{y_j/x_j} \tag{1}
\]

of the two components in a binary mixture of between 0.1 to 10, as beyond this range the error from the unknown vapor phase composition becomes too large.

Ebulliometry is generally used for binary mixtures, and in either one of two ways. The first is by preparing gravimetrically a number of samples and obtaining \( P-T-x \) data over the whole composition range. Barker’s method\(^{(b)}\) or its later variants is then used to calculate the vapor composition and then the activity coefficients. A simplified description of this calculation procedure is as follows. At low pressures, where the vapor phase can be assumed to be ideal, we have for species \( i \) at experimental point \( j \) that (Equation 2)

\[
x_{ij} y_i'(x_{ij}) P^\text{vap}_i(T) = y_{ij} P_j \tag{2}
\]

where \( y_i'(x_{ij}) \) is the activity coefficient of species \( i \) at the mole fraction \( x_{ij} \) of that species at the \( j \)th experimental point at which the total pressure is \( P_j \) and \( P^\text{vap}_i(T) \) is the vapor pressure of pure component \( i \) at the temperature \( T \) of the measurement. Summing over both species in a binary mixture at each experimental point gives Equation (3):

\[
\sum_i x_{ij} y_i'(x_{ij}) P^\text{vap}_i(T) = P_j \tag{3}
\]

by assuming an activity coefficient model, for example, the very simple Van Laar model (see, for example, Sandler\(^{(4)}\) for a discussion of various activity coefficient models), Equation (4):

\[
\ln y_1(x_{1j}) = \frac{\alpha}{(1 + \alpha x_{1j}/\beta x_{2j})^2}
\]

and

\[
\ln y_2(x_{2j}) = \frac{\beta}{(1 + \beta x_{2j}/\alpha x_{1j})^2} \tag{4}
\]

we have for the calculated pressure \( P^\text{calc}_j \) at each point (Equation 5):

\[
x_{1j} \exp \frac{\alpha}{(1 + \alpha x_{1j}/\beta x_{2j})^2} P^\text{vap}_1 + x_{2j} \exp \frac{\beta}{(1 + \beta x_{2j}/\alpha x_{1j})^2} P^\text{vap}_2 = P^\text{calc}_j \tag{5}
\]

Next, by using all the experimental data, one chooses the values of the adjustable parameters in the activity coefficient model (here \( \alpha \) and \( \beta \)) to minimize the value of

![Figure 2 Schematic diagram of an ebulliometer](image-url)
an objective function $F$ such as given in Equation (6):

$$F = \sum_{\text{experimental points } j} (P_{i}^{\text{calc}} - P_{i}^{\text{exp}})^2$$ (6)

With the parameter values so obtained, the activity coefficient can be calculated at any composition. Then Equation (2) can be used to estimate the unmeasured vapor phase compositions. Note, however, that it is more common to use more sophisticated and somewhat more accurate activity coefficient models than the Van Laar model; also, more sophisticated parameter estimation methods, such as the maximum likelihood method,\(^5\) can be used.

If the experimental data points are closely spaced, it is also possible to estimate the vapor compositions [and from those and Equation (2) the activity coefficients] without making any assumptions about the functional form of the activity coefficient model. Starting from the Gibbs–Duhem equation, and making the mild assumptions of an ideal vapor phase, and that $PV^\text{ex}/RT \ll 1$, where $V^\text{ex}$ is the molar excess volume on mixing at constant temperature and pressure, one has (Equation 7)

$$\frac{d \ln (x_1 y_1)}{dx_1} + \frac{d \ln (x_2 y_2)}{dx_2} = 0$$ (7)

which written on a point-by-point basis and using Equation (2) can be transformed into Equation (8):

$$\frac{(y_{1,j} - x_{1,j})}{y_{1,j}(1 - y_{1,j})} \frac{dy_{1,j}}{dx_{1,j}} = \frac{d \ln P_{i}^{\text{exp}}}{dx_{1,j}}$$ (8)

Replacing the derivatives by finite differences (which is why the experimental data must be closely spaced), and using the experimental pressure and liquid mole fractions and an appropriate numerical integration scheme, the value of the vapor-phase mole fraction can be computed for each liquid-phase mole fraction. This is called the synthetic method for obtaining $P-T-x-y$ data using prepared liquid compositions without the direct measurement of the composition of either phase. This method is particularly useful in mixtures such as alcohols–hydrocarbons which exhibit very non-ideal behavior. For such systems most activity coefficient models cannot adequately represent the experimental data, particularly at low concentrations of the alcohol.\(^6\)

The second method of using ebulliometry is to make a few measurements at the high-dilution range of each component, from these data to obtain the slope of the equilibrium temperature with composition at fixed pressure, and then calculate the infinite-dilution activity coefficient of each component in the other from Equation (9):

$$y_i(x_i \to 0) = y_i^\infty = \frac{P_i^{\text{exp}} - (dP_i^{\text{exp}}/dT)(\delta T/\delta x_i)_{T,x_i \to 0}}{P_i^{\text{exp}}}$$ (9)

Once the infinite-dilution activity coefficients have been obtained for each component in the other, their values can be used to obtain the parameters in a two-parameter activity coefficient model, and then to predict the VLE over the complete concentration range. Since ebulliometry is a dynamic boiling method using stills, similar to that used to obtain $P-T-x-y$ data discussed above, it is of use for approximately the same relative volatility range.

To improve the accuracy of ebulliometric measurements, differential ebulliometry is commonly used. In this measurement method, two (or more) ebulliometers are connected to the same manifold, one containing the pure solvent as a reference and the other containing the solvent into which the solute is to be added. Then, by using differential thermometry, the temperature difference as a result of solute addition is measured directly. This is more accurate than using a single ebulliometer and measuring the two temperatures separately.

In static methods, boiling does not occur as it does in the dynamic methods discussed above. Rather, a cell is almost completely filled with a liquid of known (gravimetrically prepared) composition, closed, maintained at constant temperature, and the equilibrium pressure is measured. The advantage of such a cell is that very little of the liquid is vaporized, so except for the case of a very extreme difference in relative volatility, the error introduced by a changing liquid composition as a result of partial vaporization of the liquid is small. The disadvantage of such closed-cell equipment is that any gas dissolved in the liquid results in a significant error in the measured pressure. Therefore, the liquids have to be carefully degassed (by partial vaporization or alternate freezing, evacuation, and thawing) before introduction into the static cell. With this equipment, $P-T-x$ data are generally obtained at constant temperature.

As in ebulliometry, measurements can be over the whole composition range, in which case the results are analyzed in the same manner as described above. Also, measurements can be made in just the high-dilution regions to obtain the slope of the equilibrium pressure with composition at fixed temperature. In this latter case the infinite-dilution activity coefficient of the solute in the solvent in a binary mixture is obtained from Equation (10):

$$y_i(x_i \to 0) = y_i^\infty = \frac{P_i^{\text{exp}} + (\delta P_i^{\text{exp}}/\delta x_i)_{T,x_i \to 0}}{P_i^{\text{exp}}}$$ (10)
By obtaining both infinite-dilution activity coefficients, one can fit parameters to an activity coefficient model and estimate the VLE over the whole composition range. Static cell methods have also been used to determine directly the effect on the Reid vapor pressure of the addition of an oxygenate to a real or simulated gasoline. In this case the oxygenate addition is done gravimetrically, so composition measurements are not required. The main difficulty is initial degassing the gasoline without changing its composition as a result of volatilization of the light components. Degassing of gasoline (or other mixtures) in such cases is generally done by placing the gasoline in the static cell, freezing to liquid nitrogen temperature, evacuating the headspace, thawing, and repeating the process a number of times until the vapor pressure remains constant on repeated cycles. In this way, dissolved gases such as oxygen and nitrogen can be eliminated without evaporation of the light hydrocarbon components.

The accuracy of the static cell measurements can be improved by using a differential method in which there are two (or more) static cells in the same temperature bath. The reference cell contains the pure solvent and the other cell contains solvent to which the oxygenate is to be added. A differential pressure transducer or similar device between the two cells directly measures the pressure difference resulting from addition of the oxygenate.

There also exist several gas–liquid chromatographic methods for determining infinite-dilution activity coefficients in a pure solvent. In each case the chromatographic column is loaded with the solvent and the solute is injected. By measuring the temperature, pressure, column loading, and the carrier gas retention volume, the infinite-dilution activity coefficient of the solute in the solvent can be calculated. Alternatively, by measuring only the temperature and the peak times for both a reference solute and the solute of interest, the ratio of their infinite-dilution activity coefficients in the solvent can be obtained.\(^7\)

Headspace methods provide still another technique for obtaining VLE data. In this method, an equilibrium cell similar to a static cell is used. However, the liquids are not degassed prior to a measurement, and the total pressure generally is not measured. The headspace, that is, the vapor space above the liquid, is sampled and analyzed. Consequently, in this measurement method one obtains the equilibrium vapor composition in equilibrium with the prepared liquid. As with the other methods discussed, this technique can be used over the whole composition range, or only in the high-dilution regions to obtain infinite dilution activity coefficients.

LLE data are usually obtained using relatively simple, thermostated equilibrium cells to which the components are added and stirred to obtain equilibrium as shown in Figure 3. The stirring is stopped, time is allowed to let the phases separate, and then the equilibrium phases are sampled and analyzed. Care must be used on sampling not to contaminate one liquid phase with the other. The same methods of analysis as used for VLE can also be used for LLE. Liquid–liquid phase separation for the systems of interest here occurs when water is present, and in some alcohol–hydrocarbon systems.

**4 GENERAL COMMENTS ON THE VAPOR–LIQUID EQUILIBRIUM OF OXYGENATE–HYDROCARBON SYSTEMS**

As indicated in the tables that follow, there are many data sets for binary mixtures of oxygenates with hydrocarbons, for ternary mixtures of an oxygenate with two hydrocarbons or two oxygenates with a single hydrocarbon. There are relatively few published data for an oxygenate with a multicomponent hydrocarbon mixture or a gasoline. (Given the importance of such information in the fuels industry, it is likely such data have been measured but are proprietary.)

The VLE data show that ethers and hydrocarbons form nearly ideal mixtures. Consequently, the effect of the ether on the volatility (i.e. the Reid vapor pressure) of the gasoline–oxygenate mixture is largely determined by the vapor pressure of the oxygenate. It is partly for this reason that largely C₅ and higher carbon number ethers have been used as gasoline additives. MTBE is the oxygenate most commonly used in the USA, and may...
result in a very slight increase in the Reid vapor pressure of a gasoline. Higher ethers such as tert-amyl methyl ether (TAME), diisopropyl ether (DIPE), and others, which are less volatile, have little effect on the Reid vapor pressure of the gasoline at the concentrations in which they are used, and may even result in a slight lowering. One method of lowering the Reid vapor pressure of a gasoline is to reduce its content of C4 hydrocarbons, which has resulted in a refinery stream that can be converted to MTBE. As a result, MTBE is relatively inexpensive and the mostly widely used oxygenated gasoline additive. However, there are concerns about the environmental effects of MTBE, particularly with regard to groundwater contamination.

Alcohols form nonideal mixtures with hydrocarbons. These mixtures show positive deviations from Raoult’s law; consequently, if a low-molecular-weight alcohol such as methanol or ethanol is added to gasoline, an increase in the Reid vapor pressure will result. Also, some alcohol–gasoline mixtures, particularly those containing methanol, exhibit liquid–liquid phase splitting. Many binary mixtures of an alcohol and a hydrocarbon have a minimum boiling azeotrope and/or liquid–liquid partial immiscibility. Ethanol is the alcohol most commonly used as a gasoline additive as a result of its availability from renewable or surplus agricultural products, and its low cost. Since ethanol is available domestically, it can be used to reduce a country’s dependence on foreign crude oil. Indeed, it has been used in this manner at concentrations exceeding 20 wt% in Brazil. Methanol has been used as a gasoline replacement.

There has been some interest in the VLE of gasoline with mixed oxygenates, especially an ether and an alcohol. Some of the data sets given in the tables reflect that interest.

5 REVIEW OF MEASUREMENTS OF THE VAPOR–LIQUID EQUILIBRIUM OF OXYGENATE–HYDROCARBON SYSTEMS

This review of measurements only covers mixtures of ethers or alcohols with hydrocarbons. Most of the data that have been reported are for binary mixtures, although ternary and multicomponent mixtures are also considered. The properties reviewed are VLE and LLE. The literature search was made using on-line and hard-copy versions of Chemical Abstracts, on-line Current Contents, various Thermodynamics Research Center electronic databases, the EVLM’97 electronic database, the Dortmund Data Bank, and recent volumes of Fluid Phase Equilibria, Journal of Chemical Thermodynamics and Journal of Chemical and Engineering Data.

In the tables, a tick indicates that one or more measurements have been made on a particular system. Table 1 indicates measurements made on MTBE, TAME, diethyl ether (DEE), and butyl methyl ether (BME) with hydrocarbons and with other ethers. Table 2 contains information for measurements made on mixtures of dipropyl ether (DPE), ethyl tert-butyl ether (ETBE), dibutyl ether (DBE), and diisobutyl ether (DIBE) with hydrocarbons and other ethers. Table 3 contains information on binary mixtures of methanol and ethanol with hydrocarbons–ethers. Table 4 shows the measurements made on multicomponent mixtures containing ethers–hydrocarbons–other components and Table 5 indicates measurements available on multicomponent mixtures containing alcohols–hydrocarbons–other components. Complete annotated references to the measurements on ethers are given in a recent review.

6 DISCUSSION

The experimental methods used to obtain VLE data in oxygenate–hydrocarbon and oxygenate–gasoline systems are well established, and provide no unusual challenges. Consequently, many data are available. There are a considerable number of VLE data sets for alkanes and cycloalkanes up to C₈ for mixtures with ethers. There are few measurements on alkanes larger than C₈. There are a large number of VLE measurements for mixtures of MTBE with alkenes, but none with alkynes. For aromatic compounds there exists a comprehensive
The VLE data for MTBE with various synthetic gasoline blends, and there have been a considerable number of measurements reported for MTBE–alkanes + a third component including alkanes, cycloalkanes, aromatics, ethers, and alcohols. Studies on ternary mixtures with cycloalkanes have been restricted to cyclohexane, while benzene has been the main aromatic compound studied. There is a general lack of LLE data for ternary systems involving alcohols or water.

There are no VLE measurements of TAME with hexane and alkanes larger than C₈ and limited measurements with the branched alkanes. There are sufficient VLE measurements for modeling purposes with the alkenes, though not as extensive as for MTBE, but there are no VLE measurements with the alkynes. Considerably fewer measurements have been reported for ternary mixtures containing TAME than for MTBE. While the measurements cover a cross-section of the classes of mixtures, more measurements are warranted, especially on systems containing TAME–aromatic–water, TAME–aromatic–alcohol, TAME–alkene–water, and TAME–alkene–alcohol.

There exist VLE measurements for binary mixtures with dimethyl ether (DME), DEE, and BME and a good selection of hydrocarbons. There are no measurements for DPE with alkenes, while for some mixtures, e.g. DEPE separately with heptane, cyclohexane, and benzene, many VLE data sets have been reported. There are adequate measurements on binary mixtures with ETBE and DBE, but virtually no measurements with DIBE. There have been few measurements on ternary mixtures containing ethers other than MTBE and TAME. Additional measurement should focus on the LLE for mixtures containing ethers–hydrocarbons–alcohols and ethers–hydrocarbons–water.

For binary mixtures of either methanol and ethanol with mixtures of a wide range of hydrocarbons there are many measurements of both VLE and LLE (where applicable), and there appears to be little need for any additional measurements. There are many measurements set of VLE measurements, except for ethylbenzene and propylene benzene. There are VLE data for MTBE with various synthetic gasoline blends, and there have been a considerable number of measurements reported for MTBE–alkanes + a third component including alkanes, cycloalkanes, aromatics, ethers, and alcohols. Studies on ternary mixtures with cycloalkanes have been restricted to cyclohexane, while benzene has been the main aromatic compound studied. </table>
of LLE for mixtures of alcohols–hydrocarbons–water, but there are a limited number of VLE data for such ternary mixtures. As noted, there are few data for alcohols–ethers–hydrocarbons. There are limited data for ternary alcohol–hydrocarbon–hydrocarbon mixtures and more measurements are warranted.

The three IUPAC Workshops on Vapor–Liquid Equilibria and Related Properties in Binary and Ternary Mixtures of Ethers, Alkanes, and Alkanols have stimulated much of the recent experimental work. There is now a very adequate database on VLE and LLE for many mixtures containing ethers.

ACKNOWLEDGMENTS

We wish to acknowledge the extremely valuable help of Professor J. Gmehling of the Universität Oldenburg in providing the information that allowed us to assemble the tables presented here, and to Prin Naimskul of the University of Canterbury for his help. Also, S.I.S. would like to acknowledge the financial support of the US National Science Foundation provided through grant number CTS-9521406

Petroleum residues are the remaining fraction left after the distillation of crude oil. According to the conditions of the primary distillation, a distinction is made between atmospheric and vacuum residues (VRs). Since the simplest, lighter constituents of petroleum have been separated by distillation, residues constitute the most complex fraction of crude oil and a detailed inventory of the individual compounds is impossible. Thus characterization methods will aim at giving an adequate description of the pertinent properties for a given purpose. Practically all of the existing analytical techniques have been applied: chromatographic, spectroscopic, solvent extraction, fractionation, etc. The analyst’s strategy will consist in choosing the procedure that will be able to provide limited but pertinent information, at an acceptable cost, in a reasonable time. Some easily obtained physical parameters correlate with chemical composition data. This is the case with specific gravity, viscosity, and the content of carbon residue obtained after pyrolysis. Standard test methods for the determination of these parameters have been developed.

The direct determination of compositional parameters such as aromatic carbon and hydrogen content is obtainable through nuclear magnetic resonance (NMR) spectroscopy without previous fractionation. The quantitative distribution of saturated, aromatic, and polar compounds can be measured by thin-layer chromatography (TLC) coupled with flame ionization detection (FID). The parameters obtained through various analytical techniques are generally hardly correlated since they refer to different units (e.g. mole %, weight %, or volume %) that cannot be interconverted.

A more detailed characterization requires previous separation for the preparation of simpler fractions. Although the definition of residues implies they have been produced after a preliminary distillation, short-path molecular distillation, simulated distillation by high-temperature gas chromatography (GC), and supercritical fluid extraction (SFE) apply to residues and provide the distribution of fractions possessing equivalent boiling point up to about 720 °C at atmospheric pressure. The fractions resulting from distillation cuts can subsequently be characterized. Simulated distillation by GC can be coupled with other analytical tools such as element-specific detectors or a mass spectrometer.

The separation of components in residues can be performed according to their solubility in solvents possessing increasing polarity or by chromatographic solvent elution after preliminary adsorption of the dissolved sample on a solid adsorbent. Among a wide variety of separation schemes, some have been standardized and the corresponding fractions are designated according to solubility: oils or maltenes, resins, and asphaltenes. The yield of the fractions is indicative of composition and behavior during further processing of residues.

Further characterization of fractions involves either chromatographic or spectroscopic techniques. Chromatographic methods include thin-layer, liquid-phase, and
size-exclusion modes and provide information related with composition of fractions in terms of hydrocarbon group types (saturated, aromatics, polars) and molecular weight distribution. Spectroscopic methods [ultraviolet (UV), mass, NMR] are suitable for compositional evaluation.

Physical and analytical parameters can be correlated with the distribution of structural groups existing in the hydrocarbon fraction of residues: paraffinic, naphthenic, olefinic, and aromatic (single or fused rings).

1 INTRODUCTION

Fossil fuels, excluding natural gas, represent a challenge for the analytical chemist. The molecules that they contain range from light hydrocarbons to extremely complex macromolecular structures which are the memory or fingerprints of living matter origin. The complexity originates from the process of biological material decomposition and further maturation, which are responsible for the genesis of petroleum. Considered as a global degradation, this process would give rise to the formation of a limited range of products, but, simultaneously, reactive intermediates generated during the course of degradation may recombine or associate, giving rise to the production of new entities which may exhibit a higher degree of complexity than the corresponding fragments. Prior to further processing, crude oil is first subjected to atmospheric or reduced pressure distillation; this separation yields a distillate fraction – commercialized, after adequate treatment, as gasoline, kerosene, fuel oil, etc. – and a residue. Since the simplest, lighter constituents of petroleum have been separated by distillation, residues constitute the most complex fraction of crude oil.

Owing to the associated and micellar nature of residues, an exhaustive inventory of individual components is definitively beyond reach. Hence characterization methods will aim at giving an adequate description of the pertinent properties for a given purpose. Practically all of the existing analytical techniques have been applied, but the main, hardly solvable, problem is the intercorrelation of data obtained from distinct methods. Thus, rather than pursuing a hypothetical universal method, the analyst’s strategy will consist in choosing the procedure that will be able to provide limited but pertinent information, at an acceptable cost, in a limited time.

Some easily obtained physical parameters correlate with chemical composition data. This is the case with specific gravity, viscosity, and the content of carbon residues obtained after pyrolysis. Standard test methods for the determination of these parameters have been developed.

The direct determination of compositional parameters such as aromatic carbon and hydrogen content is obtainable through NMR spectroscopy without previous fractionation. The quantitative distribution of saturated, aromatic, and polar compounds can be measured by TLC coupled with FID. The parameters obtained through various analytical techniques are generally hardly correlated since they refer to different units (e.g. mole %, weight %, or volume %) that cannot be interconverted.

A more detailed characterization requires previous separation for the preparation of simpler fractions. Although the definition of residues implies they have been produced after a preliminary distillation, short-path molecular distillation, simulated distillation by high-temperature GC and SFE apply to residues and provide the distribution of fractions possessing equivalent boiling points up to about 720 °C at atmospheric pressure. The fractions resulting from distillation cuts can subsequently be characterized. Simulated distillation by gas chromatography (Simdist GC) can be coupled with other analytical tools such as an element-specific detector or a mass spectrometer.

The separation of components in residues can be performed according to their solubility in solvents possessing increasing polarity or by chromatographic solvent elution after preliminary adsorption of the dissolved sample on a solid adsorbent. Among a wide variety of separation schemes, some have been standardized and the corresponding fractions are designated according to solubility: oils or maltenes, resins, and asphaltenes. The yield of the fractions is indicative of composition and behavior during further processing of residues.

Practically all currently practised analytical techniques are applied to the further characterization of fractions. Chromatographic methods include thin-layer, liquid-phase, and size-exclusion modes and provide information related to the composition of fractions in terms of hydrocarbon group types (saturated, aromatics, polars) and molecular weight distribution. Spectroscopic methods (UV, mass, NMR) are suitable for compositional evaluation.

Physical and analytical parameters can be correlated with the distribution of structural groups existing in the hydrocarbon fraction of residues: paraffinic, naphthenic, olefinic, and aromatic (single or fused rings).

2 COMPOSITION OF PETROLEUM

2.1 Definition of Residues

Petroleum is a mixture of liquid, solid, and gaseous hydrocarbons and other minor components, whose composition is extremely variable according to the origin of the sedimentary deposits from where it is extracted; variability in composition is also observed within a given oilfield. The hydrocarbon components of petroleum can be separated
into distinct products by atmospheric pressure distillation. The non-distillable fraction is named the atmospheric residue. The distillation end-point affects the properties of the resulting residue. The practical limit for atmospheric pressure distillation is about 360 °C, since thermal decomposition occurs at higher temperatures. During petroleum refining, the atmospheric residue is usually submitted to low-pressure distillation, yielding a distillate (vacuum gas oil) and a VR. The atmospheric pressure equivalent temperature of vacuum distillation is about 560 °C.

Residues are black, viscous material, liquid or almost solid at room temperature. The specific gravity varies from 0.95 to 1.02 and the pour point ranges between 10 and 50 °C. The yield of residue obtained from crude oil distillation is extremely variable: light oils produce as low as 10% VR, whereas some heavy oils can yield up to 70% VR. The major part of proven world petroleum reserves is composed of heavy oils and tar sand deposits. The progressive introduction of these new resources in refineries will cause an increase of the portion of residues generated by primary distillation, while the demand for light products tends to grow. As a consequence of this conflictive evolution of offer and demand, processes dealing with conversion of residues for the production of more valuable products such as transportation fuels will acquire increasing importance. In this context, a precise evaluation of the properties of residues in relation to processability will be required.

2.2 Constituents

The complexity of petroleum residues is related to the mechanisms of petroleum genesis. Crude oil is the product of decomposition of plant and animal debris in a marine environment, incorporated in sediments. Some of the constituents are directly correlated with living matter origin:

- paraffinic, naphthenic, terpene, and carotene hydrocarbons are widely distributed in living plants;
- the decarboxylation of fatty acids yields hydrocarbons;
- porphyrins (Ni or V complex of porphine derivatives) are considered as degradation products of chlorophyll and pigments.

Since the simplest, lighter constituents of petroleum have been separated by distillation, residues constitute the most complex fraction of crude oil. Attempts to fractionate residues further have been conducted since the early stages of petroleum science. As a general trend, extraction with solvents of increasing polarity provides fractions of increasing molecular weight and/or aromaticity. Solvent-extraction protocols have been developed on an empirical basis and a complex, confusing nomenclature has been derived. Some of the representative fractions obtained by solvent extraction are illustrated in Figure 1. The fraction that is soluble in light paraffins is named maltenes. Further fractionation of maltenes yields oils and resins (extracted with benzene). Asphaltenes, insoluble in paraffins, are soluble in benzene; the remaining insoluble fraction is named carbenes, which are further fractionated into carboids (insoluble in pyridine).

The yield of the defined fractions is dependent on the operating conditions: nature of the paraffinic solvent, concentration, temperature. These components are far from representative of a chemical class and their elemental composition is extremely variable (Table 1). Based on the constituents derived from fractionation, petroleum residues may conceptually be visualized as a micellar suspension of asphaltenes and resins within a continuous oily phase. The distribution of the three main components (oil, resins, and asphaltene) may be related to maturation of petroleum, and some correlations between reservoir characteristics and composition of crude oil have been observed.

3 DETERMINATION OF SOME PHYSICAL PARAMETERS OF RESIDUES

As a raw material destined to yield secondary products, residues are generally subjected to further processing. According to compositional properties such as sulfur, asphaltene, or metal content, some types of residues may possess some economic benefit as a source of fuel, as a feedstock for cracking, or for any given purpose. Others may contain exceedingly low concentrations of oily components for the manufacture of lubricating oil, for instance, that may not be economically acceptable. It is therefore necessary to perform the selection of this raw material on the basis of the subsequent end product.

In view of the extreme complexity of petroleum, in-depth analytical evaluation of residues is an exceedingly difficult task. However, recourse to sophisticated analytical techniques is not necessary for obtaining the relevant properties related to a given use. This is the case with some easily obtained physical parameters that correlate with chemical composition data: specific gravity, viscosity, Conradson carbon, refractive index. Methods for the determination of essential parameters have been standardized by major standards organizations, and test methods have been developed and published by the American Society for Testing and Materials (ASTM), 100 Barr Harbor Drive, West Conshohocken, PA 19428-2959, USA.

3.1 Specific Gravity

It was early recognized that density (relative to water) or specific gravity (sp gr expressed in g cm\(^{-3}\)) is roughly correlated with the expected yield of distillate obtainable from crude oil. Determination can be performed by means of a pycnometer or hydrometer. It is generally expressed as American Petroleum Institute (API) gravity, defined according to Equation (1):

\[
d_{\text{API}} = \frac{141.5}{\text{sp gr at } 15^{\circ}\text{C}} - 131.5 \quad (1)
\]

Since residues are highly viscous at 15\(^{\circ}\)C, the determination may be performed at higher temperature and a correction for thermal expansion applied (ASTM D1217 and D1555).

Automated apparatus (ASTM D5002) for the determination of density are based upon the change in oscillating frequency of a cell containing the liquid to be evaluated, as compared with a reference liquid (generally water). Density is proportional to the square of the variation of oscillation frequency. It is expressed as Equation (2):

\[
d_s = d_w + K(T_s^2 - T_w^2) \quad (2)
\]

where \(d_s\) is the density of the sample, \(d_w\) is the density of water at the temperature of measurement, \(K\) is an instrumental constant, and \(T_s\) and \(T_w\) are the period of vibration for the sample and for water, respectively. Provided that the temperature is controlled at \(\pm 0.1\)\(^{\circ}\)C, the observed reproducibility of determination with heavy samples such as residues is better than 0.005 g cm\(^{-3}\).

This very straightforward, easily obtained property is correlated with sulfur, nitrogen, and asphaltene content and Conradson carbon residue; as a general trend, higher heteroatoms and asphaltene content result in increased specific gravity.

3.2 Viscosity

Similarly to density, viscosity is of considerable practical importance for the petroleum industry since it is directly related to the flow characteristics of oil. Viscosity is usually expressed in centipoise (1 cP = 10\(^{-3}\) Pas) and kinematic viscosity, which relates viscosity to specific gravity, is expressed in centistokes (1 cSt = 10\(^{-6}\) m\(^2\) s\(^{-1}\)). The viscosity of residues ranges between 10\(^3\) and 10\(^7\) St.

The determination is based either on capillary instruments applying the Poiseuille equation and giving a direct measure of viscosity, or on calibrated orifice devices as the measure of flow time (t). Depending on the orifice geometry, several test methods are used and the corresponding scales of viscosity can be converted to kinematic viscosity (v) by applying the empirical Equation (3):

\[
v = At + \frac{B}{t} \quad (3)
\]

Numerical values of \(A\) and \(B\) are given in Table 2 for commonly used viscosity scales. The variation of viscosity with temperature (viscosity index, ASTM D2270) is an important expression for the use of the oily fraction of residues as a basis for the elaboration of lubricating oils. It is related to compositional characteristics of residues since it has been observed that, at comparable viscosity, naphthenic oils have a higher viscosity index than paraffinic oils.

3.3 Carbon Residue

This parameter is a measure of the amount of carbonaceous residue left after pyrolysis under an inert gas above 500\(^{\circ}\)C. It is useful to characterize the depositing propensity of residual fuels used in burning equipment.

Table 2 Coefficients for conversion of viscosity scales
or internal combustion engines. According to the test method, the numerical value is named Conradson carbon (ASTM D189), microcarbon residue (ASTM D4530) or Ramsbottom carbon (ASTM D524). Owing to the empirical character of the determination, data obtained from these methods are not strictly equivalent but can be interconnected.

Interesting relationships have been observed between Conradson carbon residue and compositional characteristics. Residual carbon is proportional to sulfur, nitrogen, and asphaltene content. An inverse correlation is observed between carbon residue and hydrogen-to-carbon ratio.

4 CHEMICAL ANALYSIS WITHOUT PREVIOUS FRACTIONATION

4.1 Elemental Analysis

Generic methods for elemental analysis are generally applicable for residue evaluation. However, the commercial importance of fuel characterization has justified manufacturers developing dedicated instruments. The specifications and range of application of commercial equipment generally exceed the requirements of current standard test methods.

Carbon content is determined through combustion in oxygen and measurement of the evolved CO$_2$. Proper control of the combustion is of critical importance for precision. It includes the use of catalytically additive, programmed sequences of previous pyrolysis and combustion, and programmed temperature ramps, which are generally proprietary. Water produced during combustion is absorbed by magnesium perchlorate. According to the instrument design, the CO$_2$ produced may be determined gravimetrically after absorption in sodium hydroxide deposited on an inert support; alternatively, the content of CO$_2$ in the collected combustion gases can be determined by infrared (IR) absorption measurement.

Hydrogen content can be obtained simultaneously along with carbon determination by gravimetry of the absorbed water formed during combustion of the sample. Specific low-resolution NMR-based methods (ASTM D4808) have been developed for the measurement of total hydrogen in residues and good correlation is obtained between NMR data and combustion data. Provided that the specific gravity of the sample is previously determined with good accuracy, the routine NMR determination of total hydrogen content does not require weighing of the sample.

Nitrogen determination involves a previous combustion of the sample. According to the type of instrument, elemental nitrogen remaining after combustion is quantified by a thermal conductivity detector, after water and CO$_2$ have been absorbed and eliminated from the combustion gases. Alternatively, nitrogen may be catalytically oxidized during combustion to nitric oxide (NO); further reaction of the combustion gases with ozone produces excited nitrogen dioxide, which is quantified with a chemiluminescent detector.

Sulfur content determination is generally performed through combustion and further evaluation of the sulfur dioxide produced in the combustion gases. Distinct methods for SO$_2$ detection are implemented in commercial equipment: simultaneous determination of carbon and sulfur can be performed by IR absorption measurement; alternatively, UV fluorescence of SO$_2$ is employed in some types of apparatus; another option consists in the absorption of SO$_2$ in iodide solution followed by coulometric measurement of the iodine produced. This method possesses the distinct advantage that it is an absolute determination that does not require calibration with standards. The range of concentration attainable by both techniques greatly exceeds the sulfur content usually found in residues; the detection limit (DL) may be as low as 100 ppb while the maximum concentration is about 5%. Higher contents can be determined after previous dilution of the sample.

Energy-dispersive X-ray fluorescence (EDXRF) is currently the most popular method for sulfur determination in many petroleum-based matrices since it does not require special skill, and measurement is fully automated. However, caution must be exercised for its application to residues since the samples are generally too viscous to be poured directly into the analytical cells. Special cells, designed for handling pastry materials, may circumvent this difficulty. Dilution of the analyte with a solvent may cause some flocculation which affects the stability of measurement. This drawback may be partly resolved by a sample spinning device incorporated in some instruments.

Metal content (mainly nickel and vanadium) determination is easily performed by EDXRF. The state of the sample is also critical: homogeneity for diluted liquid samples must be preserved, and solid-state samples require a previous preparation of the exposed surface for obtaining reliable results. The elaboration of solid-state standards requires special skill. The determination of metal content can be performed by inductively coupled plasma atomic emission spectroscopy (ICP-AES). It requires the previous dissolution of the sample, hence incomplete solubility may cause some errors due to segregation or flocculation of carboid fractions.

4.2 Evaluation Without Previous Fractionation

Analytical techniques to be used for the characterization of residues must be fast, (i.e. applicable without previous fractionation), repeatable, and quantitative. They must
also provide information regarding the distribution of chemical families, alternatively referred to as hydrocarbon group type analysis (HGTA). A rigorous analysis of residues typically involves at least one chromatographic separation step during sample preparation, which is followed by consecutive characterization of the fractions. These fractionation steps are lengthy and tedious, hence many attempts have been made to obtain information related to composition in terms of distribution of saturated, aromatic, or polar compounds, without previous fractionation. Some techniques may provide HGTA data without any previous separation. This is the case with TLC and or $^{13}$C-NMR spectroscopy.

Repeatability of analytical techniques is generally considered as a criterion for protocol selection, along with reliable quantitative determination. It must be pointed out that, in the absence of detailed information concerning individual constituents of complex mixtures, quantitation is related to internal consistency. Effectively, the definition of the considered hydrocarbon groups is often ambiguous; for example, if aromatic and saturated hydrocarbons are distinguished by a given analytical method, the distribution of hydroaromatic species between these two classes will depend on the chosen protocol. Hence internal consistency does not imply the exactness of data, and comparisons with additional analytical techniques must be made in order to assess the meaningfulness of one particular technique.

Another kind of difficulty arises from tentative comparisons of data obtained with distinct tools. It comes from the fact that the results provided by different analytical techniques are expressed in distinct units: some are expressed on a weight basis, others on a molar basis. Direct comparison of the results are meaningless, since unit conversion relies upon some external hypothesis concerning the composition of the analyte. Therefore, although analytical data are inter-related, the correlation between two distinct techniques relies upon a third external data or upon some hypothesis concerning the molecular structure.

$^{13}$C- and $^1$H-NMR are the methods of choice for aromatic carbon and aromatic hydrogen content determination (ASTM D5292). Samples need previous homogenization before dissolution in deuterated chloroform or in a mixture of carbon disulfide and deuterated chloroform. The aromatic hydrogen content (weight %) is measured by comparing the integrals of the signals in the $^1$H-NMR spectrum between 5.0 and 10.0 ppm for aromatic hydrogen and between −0.5 and 5.0 ppm for aliphatic hydrogen. Similarly, the aromatic carbon content (weight %) is measured by comparing the integral of the signal in the $^{13}$C-NMR spectra between 100 and 170 ppm for aromatic carbon and −10 and 70 ppm for aliphatic carbon, after correction for the aliphatic fraction of reference material. DLs are typically 0.1 mol% aromatic hydrogen atoms and 0.5 mol% aromatic carbon atoms. The olefin and phenol content must be below 1%.

Chromatographic techniques allow the separation and quantitation of hydrocarbon groups, after an adequate calibration procedure. High-performance liquid chromatography (HPLC) is not directly applicable to residues owing to the possible irreversible adsorption of heavy and/or polar compounds on the columns and, hence, incomplete elution.

TLC has long been applied to the separation of complex materials. It requires very simple equipment but cannot provide quantitative information. A substantial improvement of TLC has been accomplished by coupling with quantitative FID. Instead of performing the chromatographic separation on glass plates covered with a layer of porous medium, generally alumina, the sample is deposited on silica rods about 1 mm in diameter and 10 cm long, coated with a separation medium. After elution with solvents, the rods are scanned over the flame of the detector, which provides a quantitative signal. Hence this technique grants the possibility of quantifying the uneluted heavy and polar products, in addition to increasing the speed of the analysis. Hydrocarbon groups are classified according to elution sequences with selected solvent systems, a practice which allows the determination of saturated, alkylaromatic, aromatic, and polar compounds. A typical separation of a residual oil is illustrated in Figure 2.

As with other chromatographic methods, quantitative results are based upon absolute calibration, which requires a previous preparative chromatographic step in order to obtain external standards. However, a rapid
internal calibration procedure has been developed.\(^{(1)}\) Results are obtained on a weight % basis.

Small-angle X-ray scattering has been applied to the determination of the mean molecular weight of residues, since this parameter is related to the radius of gyration obtained from diffused intensity for diffusion angles smaller than 4°\(^{(2)}\)). This technique provides good agreement with molecular-weight data for asphaltene fractions obtained by gel permeation chromatography (GPC). In the case of raw and hydrotreated residues, polydispersity is evidenced.\(^{(2)}\)

5 FRACTIONATION

The purpose of fractionation is the production of a significant amount of different fractions of the residue for further characterization. The composition of the fractions is supposedly simpler than that of the whole sample, thus allowing more specific analytical techniques to be applied. Owing to the extreme complexity of residues, it is clear that an infinite variety of fractionation schemes can be imagined and that the definition and properties of the resulting fractions will depend strongly on the applied procedure. The general goal is to obtain a classification based upon some difference in chemical properties. However, the presence of many multifunctional compounds and the wide distribution of molecular weights are the cause of overlapping of fractions. Hence, owing to the impossibility of defining an absolute scheme of separation, reproducibility must be considered as the only pertinent criterion. As a consequence, the standardization of fractionation protocols is of primary importance, although they are partly based upon empirical practice.

5.1 Solvent Extraction

Numerous separation schemes have been developed for the preparation of fractions from residues. Some proposed fractionations are illustrated in Figure 3(a) and (b). No standard methods have been elaborated. The only exception concerns the precipitation of asphaltenes with \(n\)-heptane (ASTM D3279). The properties of the generic fractions (asphaltenes, maltenes, resins, wax, and oils) are obviously dependent upon the chosen solvent sequence. For instance, the yield and properties of precipitated asphaltenes vary with the number of carbon atoms in the paraffinic solvent, temperature, relative volume of solvent, and contact time.\(^{(3)}\) Consequently, the terminology of the fractions obtained cannot be considered as representative of a class of compounds. The positive aspect of solvent fractionation is the complete recovery of material without loss through irreversible adsorption, as occurs in chromatographic separation techniques. The use of large volumes of solvents and the tedious, lengthy character of the separation procedure advocate the use of alternative methods.

5.2 Adsorption Chromatography

Chromatographic procedures involve the previous adsorption of a solution of residue on a solid adsorbent. Consecutive elution with solvents yields fractions, characterized by the polarity of the corresponding elution solvent. Since asphaltenes are irreversibly adsorbed, prior separation must be considered, applying a standard

\end{figure}
PETROLEUM AND LIQUID FOSSIL FUELS ANALYSIS

method. The textural and surface properties of the solid adsorbent directly influence the separation process, hence reproducibility of the solid phase must be guaranteed for the credibility of the analytical method.

The United States Bureau of Mines/American Petroleum Institute (USBM/API) method, involving the separation of acidic and basic compounds on ion-exchange resins, is described in Figure 4. The neutral eluting fraction is further fractionated by complexation with FeCl₃, yielding neutral nitrogen compounds and an oil fraction, consecutively separated on a silica–alumina column into saturates and aromatics.

The saturates–aromatics–resins–asphaltenes (SARA) method consists in a simplification of the USBM/API scheme. Instead of using separate columns, the consecutive ion-exchange resins and complexation materials are packaged in a single column. Two methods have been standardized (ASTM D2007 and D4124). Various separation, chemical treatment, and complexation procedures have been described. The main drawback of all of these fractionations is that they are labor intensive and expensive, since they require large quantities of solvents and column packing. Furthermore, they were designed for preparative purpose in view of the subsequent characterization of the extracted fractions by analytical techniques. The recent evolution of analytical instrumentation towards ever more miniaturized systems eliminates the need for the production of large quantities of fractions since microgram quantities are now sufficient for most analytical determinations. As a consequence, chromatographic methods are moving from the preparative to the analytical scale.

Open-column liquid chromatography (LC) is advantageously replaced by medium- or high-pressure HPLC, which gives a much better resolution, requires smaller amounts of sample and is faster. Heavy and polar compounds are irreversibly adsorbed, causing column deterioration and incomplete elution, but this problem can be circumvented by an appropriate choice of stationary and mobile phases and column backflushing. The detection and quantitation of eluted fractions can be performed with a variety of detectors based upon refractive index, UV absorption, evaporative light scattering, etc. The coupling of HPLC with spectroscopic techniques can provide the direct analytical characterization of eluting fractions. Some hyphenated methods are described later.

5.3 Short-path Molecular Distillation

Although the definition of residues implies they have been produced after a preliminary distillation, short-path molecular distillation can yield additional distillate from

---

**Figure 4** The USBM/API separation procedure.
5.4 Simulated Distillation by High-temperature Gas Chromatography

Simdist GC consists in the injection of a diluted sample into a precolumn (tubing diameter equivalent to column diameter). The column temperature is programmed and the vapors are continuously directed to a nonpolar gas–liquid capillary chromatographic column by an inert carrier gas flow and coupled with FID. The column performance in terms of resolution is not critical since the objective is not to perform a detailed separation but to obtain a global signal. Initially designed for distillate characterization, the range of application has been considerably extended since the introduction of stationary phases withstanding temperatures up to 440 °C. The control of the hot-wall temperature up to 350 °C allows consecutive fractions to be prepared; it allows the production of 30–50% of distillate fraction from a VR. The mean molecular weight of the heavier distillate fraction may be as high as 800, corresponding to a 700 °C equivalent boiling point at atmospheric pressure.

5.5 Supercritical Fluid Extraction

Supercritical fluids possess unique solvation properties and can be used as a mobile phase in chromatographic processes using either packed HPLC-type columns or capillary GC-type columns. According to the scale and objective of the separation (analytical or preparative), the process is referred to as supercritical fluid chromatography (SFC) or SFE. The most common and attractive fluid is CO2, which is nontoxic and can be easily separated from the eluting material. Similarly to other chromatographic techniques, SFC can be coupled with standard detectors (FID, UV, etc.) and hyphenated with chromatographic or spectroscopic techniques. It has been applied to hydrocarbons group determination in residues and a comparative study with LC illustrated good quantification for the evaluation of saturated, aromatic, and polar compounds.

Alternatively, simulated distillation can be achieved by SFC at moderate temperatures (150 °C) with capillary columns and gives a similar boiling-point distribution to high-temperature GC.

6 CHARACTERIZATION OF FRACTIONS

6.1 Determination of Molecular Weight

A distinction must be made between colligative methods (based upon the modification of physical properties of solutions) and hydrodynamic methods. The former give access to the number-average molecular weight, \( W_n \), and the latter, concerned with the apparent molecular size, allow the value of the weight-average molecular weight, \( W_w \), to be determined.

In the former group of methods, cryometry and ebullioscopy have now largely been replaced by vapor pressure osmometry, which is easily automated. Instead of a direct determination of osmometric pressure, the flow of vapor from the pure solvent to the solution of sample is estimated through its thermal effect. The range of application is approximately 500–5000 (ASTM D2503).

The latter group of methods includes light scattering and viscosity. When a solution is illuminated by monochromatic light, the diffused intensity, extrapolated to zero concentration of solute, is a function of the radius of gyration of dissolved molecules, which in turn can be correlated with the mean molecular weight, introducing the variation of refractive index with concentration. The practical range of application is limited to molecular weights \( > 500 \).

The Mark–Houwink law establishes the relationship between intrinsic viscosity \([\eta]\) and molecular weight, \( W_w \) (Equation 4):

\[
[\eta] = K W_w^n
\]
The coefficients $K$ and $\alpha$ are related to molecular geometry, hydrodynamic behavior and solvent properties. Hence this is an indirect determination of molecular weight which can be applied over a wide range. A simplified standard method (ASTM D2502) has been proposed for petroleum-based fractions in a limited molecular-weight range (250–700). The ratio of weight-average to number-average molecular weight ($W_w/W_n$) is termed the polydispersity index and characterizes the heterogeneity of the sample. For instance, values as high as 4 can be observed for nonfractionated heavy crude samples, whilst that of asphaltene fractions is ca. 1.3. This indicates that the determination of a mean value of a given property of a complex, extremely dispersed sample is meaningless and that the information it provides is too vague to be useful.

As a consequence of the complexity of residues and fractions, the distribution of molecular weights is more meaningful than the mean value. It can be obtained by size-exclusion chromatography (SEC). In this technique, molecules are separated according to size variation in solution through permeation into the porous structure of a solid. The column packing generally consists of small particles (5–100 µm) of styrene–divinylbenzene copolymers possessing a pore structure in the range 10–100 nm. Elution is performed with solvents such as toluene, tetrahydrofuran, and chloroform. A large variety of detection methods can be applied, e.g. refractive index, UV absorption, fluorescence, and evaporative light scattering. Calibration of molecular-weight distribution is performed with polystyrene standards or normal paraffins for smaller values of $W$.

### 6.2 Determination of Aromatics and Saturates

The distribution and content of aromatic hydrocarbons in oil and oil/aromatic fractions is easily obtainable by UV absorption spectrophotometry, the experimental background of which is well established. The exploitation of UV absorption spectra is based upon multicomponent analysis, which in turn relies upon the additive contribution of each component to the total absorbance at selected wavelengths. Typical contributions of wavelength ranges are as follows: monoaromatics, 195–200; diaromatics, 225–235; triaromatics, 250–258; chrysene, 260–269; tetrabenzins, 280–289; pyrenes, 332–350; and heavier polyaromatics, 385 nm.

Calibration consists in establishing a calculation matrix based upon known samples. Since no clear relationship exists between the molecular structure of a given compound and absorbance, many interferences may affect quantitative analysis. A correction for some identified interfering classes of compounds is possible in the calculation matrix. This is the case for heterocyclic compounds and pyrenes. However, other spectral interferences are more subtle and may be overlooked in commonly practiced analytical methods. For instance, the interference caused by benzoquoranthrenes is structure dependent: $g$, $h$, and $i$ isomers interfere, whereas the $j$ isomer does not. As a consequence of variable interferences, UV spectrophotometry may be considered as a fast, comparative method for the continuous monitoring of samples whose composition varies within restricted limits. Results are expressed as mole % aromatic content.

Low-resolution, high-ionization-voltage mass spectrometry (MS) has long been used for the quantitative determination of saturates and aromatics in oil fractions (ASTM D2786). The method relies upon the resolution of a calculation matrix which accounts for the contribution of different classes of aliphatic and aromatic compounds to the production of selected ion fragments. A different approach consists in the use of a low ionization potential (field ionization) in order to maximize the yield of molecular ions. However, since numerous interferences occur, recourse to high resolution is necessary in order to discriminate compounds possessing an equivalent nominal molecular weight but different elemental compositions. The scope of the technique is limited to those products that are volatile at the maximum allowable source temperature (usually 350 °C), corresponding to a 550 °C atmospheric boiling temperature.

$^{13}$C- and $^1$H-NMR spectroscopy (section 4.2) obviously can be applied to fractionated products for the determination of aromatic and aliphatic carbon and hydrogen.

### 6.3 Hyphenated Techniques

As mentioned earlier, an infinite variety of fractionation schemes and corresponding products can be designed. It therefore seems more efficient to proceed to a continuous determination of one specific property of fractions along with the separation process. This approach constitutes the basis for numerous combinations of analytical methods coupled with separation techniques.

Typically, a chromatographic method may be coupled with another chromatographic technique; numerous methods use the coupling of HPLC columns. The combination of normal-phase, reversed-phase, charge-transfer, and size-exclusion modes can be used to separate fractions of different polarity or size, and subsequently proceed to a further separation based upon another process. Similarly, the combination of HPLC and GC can be contemplated for volatile fractions. Chromatography can also be coupled with a specific detector, either an element-specific or multielement detector (e.g. atomic emission detector), or with a spectroscopic technique, e.g. TLC coupled with a UV detector or GC coupled with MS.
6.4 Determination of Individual Compounds

The presence of some target compounds in residue fractions deserves particular attention. This is the case with carcinogenic polycyclic aromatic hydrocarbons (PAHs), which can be concentrated on reversed-phase columns and further quantified by taking advantage of the selectivity of fluorescence detectors.

Metalloporphyrin complexes can be used as potential fingerprints of the origin of crude oils. They are selectively extracted from neutral heavy fractions with acetonitrile and may be further separated into nickel and vanadium groups by HPLC.

7 RATIONALIZATION OF ANALYTICAL DATA

The preceding fractionation and characterization techniques roughly distinguish paraffinic, naphthenic, and aromatic structures in residues. Since establishing an exhaustive inventory of individual molecular components in residues is a hopeless endeavor, structural group analysis (SGA) will attempt to describe the statistical distribution of structural elements, irrespective of the way in which they are combined in molecules, thus providing information intermediate between elemental and molecular analysis. Molecules in heavy fractions may simultaneously contain aromatic and naphthenic rings and paraffinic chains. Hence they cannot be classified according to the previously described separation schemes and they are better described in terms of structural fragment composition.

7.1 Determination of Structural Parameters from Physical Properties

In the early age of the petroleum industry, several simple methods, based upon the analysis of numerous samples, were developed for determining the distribution of carbon atoms (number of rings, percentage of carbon in rings) and hydrogen content from elemental analysis, refractive index, and density determination. For example, the n—d—M method (ASTM D3298) is based upon the measurement of refractive index, density, and molecular weight at two temperatures. It allows the calculation of the percentage of aromatic carbon atoms, carbon atoms in ring structures, mean number of rings, and mean number of aromatic rings.

Numerous variations of these methods have been proposed, e.g. dispersion—refraction, density temperature coefficient, molecular weight—refractive index, and viscosity—density—refractive index. Owing to the empirical character of these methods and the need for some tedious measurements, spectroscopy-based SGA methods are currently preferred.

7.2 Determination of Structural Parameters from Spectroscopic Methods

1H-NMR and later 13C-NMR have been extensively used to provide average molecule parameters as a description of petroleum derived fractions. The assignment of 1H- and 13C-NMR signals can be more refined than the simple distinction between aliphatic and aromatic entities presented in section 4.2. A summary of structure assignments is presented in Table 3. Thus, combining 1H- and 13C-NMR data, the following distribution of carbon atoms per mean molecule can be deduced: saturated carbon to aromatic ring; peripheral carbon in condensed ring systems; internal carbon in condensed ring; paraffinic methylene carbon further than α to aromatic ring; and paraffinic methyl carbon.

Additional parameters can be derived by combining NMR data and molecular-weight measurement, such as the degree of substitution of aromatic structures, the number of aromatic rings per molecule, and the number and length of alkyl substituents. This approach gives average parameters that may not provide information about the actual distribution of components in the mixture. The functional group analysis approach developed by Petrakis et al. is based on the premise that although the molecules in heavy fractions may be extremely complex, they are composed of a limited number of functional groups. The chosen set must account for experimental data, and it must be as concise as possible. An illustrative list of functional groups is described in Table 4. Additional groups may be accounted for, provided that their contribution is relevant and in agreement with analytical data (e.g. oxygen or

Nitrogen atoms. The concentration of the specified set of functional groups is introduced into a set of balance equations concerning the different structures (carbon and hydrogen atoms at different positions) derived from experimental data, with their respective stoichiometric coefficients. The resulting information has a definite superiority over average values of structural groups in the sense that it can be used for the quantitative description of complex samples and as a tool for elucidating reaction pathways. The contribution of estimated functional groups to thermodynamic properties, such as heat capacity, can be evaluated.

This article discusses productivity enhancement which involves using an on-line digital process refractometer to determine the viscosity index (VI) of lube oil stocks. Since lube oils are Newtonian fluids, refractive index (RI) can be related to VI. A real-time continuous measurement of the RI has eliminated sampling, improved product consistency, reduced waste and has helped to optimize the process.

1 INTRODUCTION

In lube oil production the measurement and control of viscosity is vital. Goals such as uniform product quality and minimum waste can be achieved by continuous monitoring. Unlike periodical sampling, continuous monitoring provides instant feedback about changes in the process. This instant feedback is then used to control the process in real time.

2 VISCOSITY OF LUBRICATING OIL

Viscosity is the internal resistance to a shear force and is a complex property of a fluid. It is, however, a measurable property. The dynamic viscosity of a fluid will change with temperature and the way in which the shear is applied.

Thicker fluids have a higher viscosity. Dynamic viscosity is defined by Equation (1):

\[ \mu = \frac{\tau}{D} \]  

where \( \mu \) is the dynamic viscosity (N s m\(^{-2}\) or poise), \( \tau \) is the shear stress (N m\(^{-2}\)) and \( D \) is the shear rate (s\(^{-1}\)).

Fluids can be divided into two groups: Newtonian and non-Newtonian (see Figure 1). A Newtonian fluid is one in which the viscosity is independent of the shear rate. Examples of Newtonian fluids include water and oils. A non-Newtonian fluid is one in which the viscosity will differ depending upon the shear rate used in making the measurement. There are several types of non-Newtonian fluid. In order to obtain an accurate reading in a non-Newtonian fluid, the shear rate at which the measurement is made must be specified.

The kinematic viscosity of a fluid is the ratio of dynamic viscosity to density. Kinematic viscosity (\( \nu \)) is expressed in either centistokes (cSt) or millimeters squared per second (mm\(^2\) s\(^{-1}\)) and is defined by Equation (2):

\[ \nu = \frac{\mu}{\rho} \]  

where \( \rho \) is the density (kg m\(^{-3}\)).

Lubricating oils with higher kinematic viscosity create a thicker film of the oil that will cling to a metal surface. Depending on the end-use of the lube oil, it may need to be very thin and free flowing or thick with a high resistance to flow. The rate of change of kinematic viscosity with temperature is the VI; it is a unitless number. A high VI indicates a smaller decrease in the kinematic viscosity with increasing temperature (see Table 1).

3 BASIC LUBE OIL PROCESSING

Crude oil is a mixture of various types of hydrocarbon. The crude oil type influences the VI of lube oil that can be produced. Naphthenic crude oils contain cyclic compounds and are used to produce low to medium VI base oils. High VI base oils are commonly made from paraffinic crude oils that contain mostly straight-chain hydrocarbons. The challenge to the refiner is the selection and blending of the crude type to optimize the production of the desired lube oil.

This crude oil mixture is first separated into useful fractions by thermal distillation. The products from thermal distillation are enhanced later by other unit processes such as catalytic cracking, hydrotreating, dewaxing and solvent extraction. Lube oil stocks contain wax and other contaminants that need removal before blending into products such as motor oils. This further processing helps to maximize the desired lube oil production.
The propane extraction process removes undesired components. Propane is unique because it extracts both on the basis of molecular weight and by chemical structure. The propane is recovered with the resulting products being asphalt and deasphalted oil feed for the solvent extraction process.

Extractive solvent processing follows propane deasphalting. The most common extractive solvents used are furfural and phenol. The purpose of solvent extraction is to improve the VI, oxidation resistance and color of the lube base stock. After the solvent extraction process is complete, the resulting waxy stream is further processed either chemically or by catalytic methods.

There are several types of dewaxing solvent used in the refining industry. The most common solvent is MEK (methyl ethyl ketone). Most refiners charge the stream produced from the furfural or phenol refining unit to the dewaxing unit.

The types of result achieved in catalytic treatment depend on the type of catalyst used and the severity of the treatment. The pour point of a hydrocarbon liquid is the temperature at which it will no longer flow. Improving pour point is best achieved using a single catalyst. For color improvement and oxygen stability more than one catalyst may be required. Color improvement is directly related to the type of catalyst and operating conditions of the unit.

A summary of the various types of lube oil processes is given in Table 2.

The use of a reliable in-line measurement technique can eliminate sampling and time-consuming laboratory testing for the determination of the VI of oil. The laboratory method for the determination of the VI of lube oil is the American Society for Testing and Materials (ASTM) D 2270-93, the VI is the rate of change of the measured kinematic viscosity. For the calculation of a VI when the kinematic viscosity at 100 °C is less than 70 cSt Equation (3) is used:

\[
VI = \frac{L - U}{L - H} \times 100
\]

where \( U \) is the kinematic viscosity at 40 °C (mm² s⁻¹ or cSt), \( L \) is the kinematic viscosity at 40 °C of an oil of 0 VI (from Table 1 of ASTM D 2270-93) and \( H \) is the kinematic viscosity at 40 °C of an oil of 100 VI (from Table 1 of ASTM D 2270-93). For \( v \) values greater than 70 cSt the ASTM method uses another equation.

The relationship between RI and VI for a given crude or crude blend is established by laboratory testing and then confirmed by sampling at a prescribed interval. Based on the results of the laboratory tests, ASTM D 1747-89, the refinery can set target RI values for the process. The final quality or final VI of the lube oil can then be controlled and measured by the in-line refractometer.

## 4 REFRACTIVE INDEX THEORY

RI is a measure of the amount of bending or refraction that occurs when light passes from one medium to another. This is caused by the change in the speed of light in each medium. In addition to varying with the medium, the response changes with the concentration of the dissolved solids. The mathematical equation for this principle is known as “Snell’s law” defined as, Equation (4):

\[
\sin i = n \sin r
\]
where \(i\) is the angle of incidence, \(r\) is the angle of refraction and \(n\) is the RI.

The critical angle (Figure 2) is the point or angle at which light refraction ends and total reflection starts. This is defined by Equation (5):

\[
\sin c = \frac{n_1}{n_2}
\]

(5)

where \(c\) is the critical angle, \(n_1\) is the RI of first medium and \(n_2\) is the RI of second medium.

However, it was not until 1874, with the invention of the refractometer by Ernst Abbe, that RI became practical to measure.

5 IN-LINE REFRACTOMETER

The primary measurement of a process refractometer is RI. This is done by directing light through a prism at various angles to the interface between the prism and the liquid being measured. This creates both refracted and reflected light rays that form a light and dark image. The critical angle occurs at the transition or borderline that differentiates the refracted and reflected portion of this optical image. This borderline position changes with RI and/or the dissolved solids concentration.

The in-line process refractometer uses a charge-coupled device (CCD) microchip to determine the position of the borderline and relate its position to RI. The use of the CCD microchip replaces the human eye that serves this function in the case of a hand-held and/or a laboratory refractometer. The CCD then converts this optical image into a digital signal (Figure 3). This conversion eliminates drift and increases the stability of the measurement. The second component to any RI measurement is temperature: RI is temperature dependent and, hence, a correct temperature measurement is important. Only by the correct combination of these two measurements can a stable, accurate and reliable RI value be generated.

The relationship between °API or API gravity of an oil (a density term used in the petroleum industry) and RI is proportional. °API can be defined by Equation (6):

\[
°API = \frac{141.5}{\text{specific gravity of the oil}} - 131.5
\]

(6)

Specific gravity equals the density of liquid divided by the density of water. Water has a specific gravity of 1.0 and an API gravity of 10°. Materials with high API gravity are lighter and lower in density. The reverse is true for specific gravity.

However, RI can be directly measured whereas °API is calculated. This is why RI has been found to be a more reliable process parameter to monitor. The range of RI at 70 °C for a lube oil varies from 1.4400 to about 1.5000. An accurate in-line determination of RI is required because a change in the RI between 0.0007 to 0.0010 RI units, can result in a change of 1 unit in the final VI of nonprocessed lube oil. The exact magnitude of the change will depend on the oil type and the initial °API of the oil being processed. In general, the change in VI for heavy, high °API, naphthenic-type feeds tends to be greater than that of lighter, lower °API, more paraffinic feeds (Figure 4).

Mounting and location of the prism are important to the measurement. As well as improving the temperature indication, being angled and having an intrusive design promotes self-cleaning. The angle creates turbulent flow and locating away from pipe walls keeps the prism at the same temperature as the process fluid. A minimum velocity is maintained so that self-cleaning can occur and a fresh sample is constantly provided for the measurement. In some lube oil applications the self-cleaning is sometimes supplemented by a steam washing system. The in-line refractometer should be installed in a sample line so that temperature variations are minimized; temperature control is usually done by a heat exchanger. This location assures that any sample collected and later tested by the laboratory will be identical to that measured by the in-line refractometer (Figure 5).
6 CASE STUDIES

A large lube oil producer has installed several digital process refractometers in their refineries. These units have been in operation for several years. According to one process engineer associated with the project the digital process refractometers operated as expected and provided accurate and repeatable RI numbers. This on-line RI information is then used to predict the final lube oil VI and to adjust the efficiency of the process.

Several types of process change can affect VI, such as, blend stock source and extraction tower temperature. There is a finite residence time for the effect of a given process change to pass through the process unit. However, laboratory samples can be delayed and their results determined well after the unit has been affected. The installation of an in-line device is required to establish an exact correlation between process changes and VI (Figure 6). This delay time can increase production costs and reduce product quality.

A major gulf coast lube oil facility produces a variety of motor oil and lubrication products. Their process is based on Chevron’s ISODEWAXING® technology and is designed to operate on a wide variety of crude oils.

Owing to variability of the feed, a reliable and accurate method is required to characterize the process. This refinery makes frequent changes in the crude feed. Changes in the crude feed increase the risk of making off-target product which may contaminate a finished product tank.

Contamination of a finished product tank can adversely affect the refinery in several ways. First, it reduces overall refinery capacity owing to a lack of storage for new production. Second, it tends to reduce net unit feed because the off-test material must be blended in with fresh feed. This is especially costly if the affected unit is currently at its maximum capacity.

This location has two digital process refractometers installed in its new catalytic hydrotreater dewaxing lube oil unit that processes about 10 000 barrels per day or

420 000 US gallons per day. These refractometers were commissioned early in 1997; the start-up was very simple. According to the process engineer, both units have been stable and very reliable. This plant has found the RI measurement useful during crude blend shifting. The RI reading is used to identify and predict when possibly off-test VI material is going into final product tanks and when best to collect lab samples. If the RI reading is outside the normal level it has been found that the VI will also be outside the required specifications. In this case, the off-test product is diverted from the finished product tank. Operations estimated that because they have avoided producing off-test material, the pay back time for the refractometer was very short, based on the price of lube oil (see Table 3).

7 CONCLUSION

Both viscosity and RI are physical properties of a fluid. They have both been measured by one or more methods for several years. Although laboratory test procedures and protocols are well established in a modern refinery, they can never respond with the speed of an in-line instrument. The profitability of the lube oil unit is related to its ability to obtain quick, accurate and reliable VI information in order to make the correct adjustments to the process.

The following can be stated about the relationship between RI and lube oil VI:

- RI measurement of lube oils has traditionally been done in the laboratory, but now it has moved into the process environment. The process measurement of RI is now reliable, simple and cost effective.
- An in-line process measurement of RI can be used as a real-time predictive tool for the final VI of lube oils in the quickly changing production environment. A quick and accurate response is needed in order to optimize production.
- RI can identify and predict when possibly off-test VI material is going into finished product tanks. Contamination of a finished product tank can adversely affect both the economics and operations of a refinery.

References

The chemical complexity of petroleum products has, until recently, precluded calculational techniques based on a definitive analysis of the molecular species involved. Instead, readily observed or easily (quick and inexpensively) measured macroscopic properties (gravity, boiling range, etc.) have been used to correlate information empirically. In some instances, the predictions have been “tweaked” on a local data-centric basis or extended by quasi-theoretical analysis.

Recent computer-aided advancements in multi-variate electromagnetic emission, NMR (nuclear magnetic resonance) and/or MS (mass spectroscopy) analyses allow for the reliable and repeatable use of much more detailed experimental data. The ability to speciate cuts by individual chemical components will revolutionize both refining and regulation of refined products in response to the availability of quality data.

So why would one bother with older analysis and prediction methods? It is likely, given the operational sophistication and investment costs needed to deliver this highly speciated information properly, that the old ways will die but slowly. Most refineries and petrochemical plants try to get by with the minimum amount of expensive on-line analyzers. Multivariate data generation is not yet at a state where it can easily be used for real-time process or even product quality control. This barrier will exist for some time to come.

The historical development of crude oil processing technology has generated a great volume of data and “general” correlations, some contradictory. Most of the data upon which these methods are based have been around for 60 or more years. Many have withstood the “test of time”, being examined and verified by numerous researchers both public and private. Some of the precision of the older data may not be as good as what is generated today, but new entries to various refinery products’ databanks seem to confirm the validity of the best of the older procedures and data.

The classical methods allow one to impute several otherwise unavailable characterizing pieces of data. It is essential that those engaged in the design and analysis of refinery units (which have multiple feed and product streams) become familiar with classical terminology and techniques, and eventually acquire an intuitive sense of what constitutes the “best answer” when confronted with several conflicting alternatives. The subject of this article is the proper methodology of imputing this knowledge from whatever data are at hand.
1 HYDROCARBON CHARACTERIZATION AND PROPERTY PREDICTION VIA INSPECTION PROPERTIES

1.1 Introduction

The chemical complexity of petroleum products has, until recently, precluded calculational techniques based on a definitive analysis of the molecular species involved. Instead, readily observed or easily (quick and inexpensively) measured microscopic properties (gravity, boiling range, etc.) have been used to correlate empirical information. In some instances, the data have been “tweaked” on a local “crude-feed” basis or have been extended by quasi-theoretical analysis. A list of the more common inspection properties for petroleum-derived fuels products is given in Table 1.

Recent computer-aided advancements in multivariate electromagnetic emission, NMR and/or MS spectral analyses allow for the use of such experimental data in real time. The ability to speciate cuts by individual chemical components will revolutionize both refining and regulation of refined products in response to the availability of quality data.

So why would one bother with older analysis and prediction methods? It is likely, given the sophistication and investment costs required to deliver this highly speicated information properly, that the old ways will not die out for a long time; some of them never. Most refineries and petrochemical plants try to get by with the minimum amount of expensive on-line analyzers. Multivariate data generation is not yet at a state where it can easily be used for real-time process or business control. It is likely that this barrier will exist for some time to come.

The classical methods allow one to impute several otherwise unavailable characterizing pieces of data. It is essential that those engaged in the design and analysis of refinery units (which have multiple feed and product streams) become familiar with classical terminology and techniques, and eventually acquire an intuitive sense of what constitutes the “best answer” when confronted with several conflicting alternatives. The subject of this article is the proper methodology of imputing this knowledge from whatever data is at hand.

The historical development of crude oil processing technology has generated a great volume of data and “general” correlations, many contradictory, and which can be a source of frustration to those accustomed to relatively rigorous true component calculations. Most of the data upon which these methods are based have been around for 60 or more years. They have withstood the “test of time”, being examined and verified by numerous researchers both public and private. Some of the precision of the older data may not be as good as what is generated today, but new entries to various refinery products’ databanks seem to confirm the general efficacy of the older methods and data.

Then, too, a mere listing of components and relative amounts does not always mean that the important processing properties of the stream can be estimated...
accurately. In cases of MWs and critical properties, the multispectral analyses predict well. In the areas of transport properties, such as viscosity and thermal conductivity, predictions from mixtures of pure components, by most published research work, have been patchy at best. Although some efforts have been made public in quantifying the contributory effects of molecular structural interactions, little has been published that is of general value. There will certainly be more opportunities for research in this area, but the current technology will be used to augment and extend pure lab data for the next 10–20 years.

In any event, these correlations have been useful to the author and can be utilized, for lack of any other need, as a check on the values derived from more directly analytical methods.

For editorial purposes, several liberties have been taken in construction of this article. For one, several acronyms are employed in place of explicitly named properties. For example, AP is aniline point, SG is specific gravity, etc. We make so many references to such properties here, both in the text and in equations, that to spell them out time and again would drastically increase the length of the article. We also have relied heavily on two primary compendia of timely information. These are the ASTM standards, and the API Technical Data Book. Mention of any of these sources in the articles should be considered as an implicit reference. To repeatedly denote them separately would increase text length dramatically. Then too, each of these magnificent documentation sources are constantly being revised and improved. The reader is strongly advised to refer to the latest versions of each relevant document, which are readily available from the two organizations, as well as from other many other purveyors of technical information. Finally, several of the correlations and calculation methods are reported here in units other than standard SI, the default for this encyclopedia. In some cases where clarity and brevity allow, we have provided both sets of units. In other cases, we have reported the units as described in the original information source, to avoid transcription errors or in cases where prevailing standards and specifications (or simply potential user bias and familiarity) call for the values in, perhaps, Imperial standard units as opposed to metric. The reader is advised to bear this in mind, especially when dealing with correlations requiring absolute temperatures, such as with the Kelvin or Rankine scales.

**1.2 Summary Description of Petroleum Inspection Properties**

Among many different types of petroleum properties, the following are the ones that should be considered in order to understand petroleum processing technologies.

The first set of inspection properties are typically measured as a normal daily or even hourly quality control effort. In a few cases, on-line analyzers can be used for real-time process control. The requirement for this capability is the ability to obtain, analyze and report accurately the findings to the process feedback control system on a timely basis (30 s to 20 min, typically).

**1.2.1 Aniline Point**

The AP is the minimum temperature for complete miscibility of equal volumes of aniline and the sample under test. It is a measure of paraffinicity of petroleum fractions; the higher the AP, the higher is the paraffin content. The standard test for this method is ASTM procedure D-611.

**1.2.2 American Petroleum Institute Gravity**

The API density standard is by definition (Equation 1):

\[
SG = \frac{141.5}{131.5 + API \text{ gravity}}
\]  

Therefore, by mathematical manipulation (Equation 2):

\[
API \text{ gravity} = \frac{141.5}{SG} - 131.5
\]

The standard test for this SG of a petroleum cut is ASTM procedure D-4502.

**1.2.3 Bromine (or Iodine) Number**

The bromine number is the number of grams of bromine consumed under specified test conditions by 100 g of sample. Bromine number is a measure of olefinicity of a petroleum fraction; the higher the bromine number, the higher is the olefinic content. Iodine is sometimes used for this test instead.

**1.2.4 Cetane Index/Cetane Number: Diesel Ignition Characteristics**

The cetane number (CN) is the diesel fuel analog to gasoline octane. It is defined (ASTM D-613) as the percentage of normal cetane that must be added to heptamethylnonane in order to match the ignition characteristics of the fuel undergoing tests. Typical refinery diesel stock CNs vary from 35.0 to 50.0.

The CI is a useful calculation for estimating the CN without experiment.

**1.2.5 Cloud Point**

This is the temperature at which paraffinic waxes (or other high MW components) just start to crystallize
and cause the stock to appear cloudy or hazy. This is a constraint temperature for fuels that must perform in low temperatures (−20°F and below). Jet fuels and arctic winter gasolines are two such products. The CP is also an important characteristic of lubricants that need to perform in cold temperatures. The formation of wax crystals that can form will inhibit the lubrication effectiveness.

The standard test for this method is ASTM procedure D-2500.

1.2.6 Distillation Data (Different Types of)

1.2.6.1 American Society for Testing and Materials D-86 Distillation (760 mmHg)
- Gasoline
- Distillate

1.2.6.2 American Society for Testing and Materials D-1160 Distillation (Usually at 10 mmHg)
- Heavy oils
- Residuum
- Fractionator bottoms

1.2.6.3 True Boiling Point Distillation (15/5 Distillation at 760 mmHg)
- 15 stages and 5 reflux ratio
- Approximate true boiling temperatures
- Used for blending of fractions
- Pseudo-component generation from the distillation
- This test has several variations in common use but ASTM D-2892 is as close to a standard as exists.

1.2.6.4 American Society for Testing and Materials D-2887/D-3710 (Gas Chromatography Methods at 760 mmHg)
- Programmed GC calibrated to type (boiling range) of stocks (gasoline, kerosine, diesel, etc.). They can be readily correlated to D-86 and TBP and are quick and repeatable up to heavy ends [1000 °F normal boiling point (NBP) maximum] distillation range.

1.2.7 Flash Point

This is the lowest temperature to which the substance must be heated in air to form a mixture containing sufficient vapor to be ignited momentarily by a flame under a specific condition. The test methods used are the Cleveland open cup (ASTM D-92), Pensky Martin closed cup (ASTM D-93) and TAG closed cup standard (ASTM D-56). The FP is important in the handling of volatile products such as cleaning solvents and gasolines. For heavier stocks, the FP is used to estimate the oil’s ability to vaporize under certain conditions, which affects both the oil’s potential flammability hazard and the consumption rate of the oil.

1.2.8 Freeze Point

This parameter is similar to CP but according to a slightly different procedure. It is defined by ASTM D-2386 as the temperature at which the first solid hydrocarbon crystals, which are formed as the sample of the hydrocarbon is slowly cooled with agitation, disappear upon slight heating. Again, cold weather performance of the fuel is the critical property of concern here.

1.2.9 Octane Number: Anti-knock Characteristics

This is defined as the volume percentage of isooctane that must be mixed with n-heptane in order to match the knock intensity of the diesel fuel undergoing testing.

- Octane number of isooctane = 100.
- Octane number of n-heptane = 0.0.
- Research octane number: engine speed 900 rpm.
- Motor octane number: engine speed 600 rpm.

1.2.10 Paraffins, Olefins, Naphthenes and Aromatics Analysis (Observed/Calculated Measurement)

The PONA in a petroleum fraction is often obtained by a combination of GC, NMR and infrared (IR) methods and inspection properties or by multivariate analysis of one or more of these. There are several ASTM standards for a multitude of tests that can be used to gather this information.

1.2.11 Pour Point (American Society for Testing and Materials D-97)

The PP is the lowest temperature at which a high MW hydrocarbon mass starts to pour. A solidified quantity is slowly heated (in 3°C steps) and tilted to see if the solid mass starts to flow within 5 s. The temperature at which perceptible flow occurs is recorded as the PP. This property is useful in determining some of the processing properties of heavier cuts. Cold weather flow performance of the fuel or lubricant stock is the major concern addressed by this standard.

1.2.12 Ramsbottom Carbon/Conradson Carbon/Bureau of Mines Correlation Index

These tests determine the percentage (wt%) of residue left after pyrolytic carbonization of a petroleum fraction. This is usually done for residuum or fractionator bottoms product. They are a measure of how much coke it will
make in coking processes. All lubricating oils leave behind “carbonaceous” deposits at high temperature as well. Deposits of these materials can ultimately affect the engine’s performance.

The ASTM D-189 method is used for Conradson carbon and the ASTM D-524 method for Ramsbottom carbon contents. The BMCI is another method of defining the carbon residue of shale oils.

1.2.13 Refractive Index

The RI represents the ability of a liquid to bend and distort the travel path of light across the air–liquid boundary. It is a fairly simple and repeatable test. RI is a basic parameter for determination of aromatics content and, when combined with viscosity, provides a quality estimate of MW. ASTM D-1218 is the controlling standard.

1.2.14 Reid Vapor Pressure

RVP is an approximation of the vapor pressure of naphtha and distillate range petroleum fractions at 100°F, the estimated automobile carburetor or injector inlet temperature. RVP also gives the refiner an indication of how much light hydrocarbons (especially n-butane) are contained in a petroleum fraction. Three ASTM standards, D-323, D-4956 and D-5191, are used to ensure the quality of the data.

1.2.15 Smoke Point (American Society for Testing and Materials D-1322)

The SP is a measure of burning cleanliness of jet fuel or kerosine. It is defined by the ASTM standard as the maximum flame height (millimeters) at which a fuel will burn without smoking. The SP is low for a fuel having a high smoking tendency. In general, removal of aromatic content increases the SP. An SP > 17 is generally acceptable.

1.2.16 Viscosity

Viscosity is an important control property for lube oils and often for some heavy cracked products. There are at least eight scales by which these data can be reported. For most correlations, either centipoise or centistokes is required. This may necessitate some calculations in addition to the primary measurement data one takes in the laboratory. This article will not concern itself with such conversions as they are widely presented elsewhere in the literature.

The following properties are so quickly and easily derived from basic measured inspection data that they are typically included as a part of the inter-property relationships.

1.2.17 Watson K Factor

The most important derived property (sometimes called the UOP K factor) is the Watson K ($K_W$) or characterization factor. It is defined by Equation (3):

$$K_W = \frac{[\text{weight-average boiling point (°R)}]^{1/3}}{\text{SG}}$$

It is a measure of the distribution of different types of molecules (paraffins, naphthenes and aromatics) in a petroleum fraction. The higher the $K_W$ factor, the higher is the paraffinity, and the lower the $K_W$ factor, the higher is the aromatics content. For most refinery stocks $K_W$ varies from 10.0 to 13.0 in general. Note the use of absolute temperature scales in calculating $K_W$.

Three other compositional characterization factors are used to a limited extent with petroleum fractions. These are the viscosity–gravity constant, the Huang factor and the refractive index. They will be discussed in limited detail. Most of the methods and data work done to date in this field have involved the $K_W$ factor far more than any other.

1.2.18 Molecular Weight (Derived/Measured)

The molecular weight (MW) can actually be estimated by laboratory procedures, but these are slow and labor intensive, so they are very rarely performed in an operations setting.

1.2.19 Cetane Index: Diesel Fuel Ignition Characteristics

The CI is a derived property that is roughly approximated to measured CNs. Direct analysis of CN is a difficult measurement and several correlations have been developed to permit operations to estimate the CI based on other observed properties.

1.2.20 Diesel Index

This is given by Equation (4):

$$\text{DI} = \frac{(\text{AP}) (\text{API gravity})}{100}$$

This is also an indication of paraffinicity of a petroleum fraction.

1.2.21 Temperature at which $V/L = 20$

$T$ at $V/L = 20$ is a fuel specification requirement for most gasolines. It is obtained from the TBP curve with estimates of vapor and liquid volumes where the ratio of the two is 20:1. As such, it is easier to derive than to measure.
1.2.22 Thermal Capacity and Transport Properties

This category of properties is most important in the design and prediction of refinery operations. Many of these can be measured directly in the laboratory but few with any simplicity. Derivation of values is then the preferred and a usually accurate alternative in this case.

The properties considered here are outlined below.

1.2.22.1 Heat of Combustion

An important property of all fuels is the heat of combustion, since this is a measure of the energy available from the fuel. A knowledge of this value is essential when considering the thermal efficiency of equipment for producing either power or heat. ASTM D-240 is used for the direct determination of heats of combustion of aviation gasolines and of fuel oils. Net heats of combustion of petroleum fuels vary from 45,925 kJ kg\(^{-1}\) (19,774 Btu lb\(^{-1}\)) for propane to 33,029 kJ kg\(^{-1}\) (14,200 Btu lb\(^{-1}\)) for petroleum coke. Ordinary calorimetric techniques are employed.

1.2.22.2 Heat of Vaporization

Proper and safe separation of hydrocarbons by vapor–liquid equilibria requires an accurate knowledge of the heats of vaporization. This is an important variable for calculating heating duties and thermal processing equipment sizes.

1.2.22.3 Heat Capacity of Liquid–Vapor

Prediction of liquid and vapor behavior under heat transfer conditions is of great concern. This is an important variable for calculating details of thermal processing and distillation equipment.

1.2.22.4 Thermal Conductivity of Liquid–Vapor

Prediction of this property is often an inaccurate procedure. With hydrocarbons, however, it is surprisingly good. This is also an important variable for calculating details of design and operation of thermal processing equipment.

1.2.22.5 Critical Properties

For a pure component, the critical state can be summarized by three interrelated thermodynamic parameters—the critical temperature, critical pressure and critical density. The critical temperature is defined as that temperature above which a gas cannot be liquefied by an increase in pressure. The maximum pressure that will result in formation of a separate liquid phase at the critical temperature is called the critical pressure. The density of a fluid at its critical temperature and pressure is its critical density.

When dealing with mixtures of two or more compounds, this precise definition needs some refining. In theory, there is a state in which all intensive properties of the coexisting liquid and vapor phases become continuously identical. Corresponding states correlations that depend upon a reasonable estimate of the critical state work best with what are known as “pseudo-critical” quantities. These are traditionally defined as the molar average of the critical temperature and pressure.

The following properties are typical items also measured in a normal sampling in most refineries. With the exception of the asphalt test, they all measure contamination levels. They have little bearing on general predictive techniques and will not be mentioned beyond this summary.

1.2.23 Penetration Index for Asphalt (Observed Measurement)

This is the depth (in millimeters) that a standard needle penetrates vertically into a sample of the asphalt material under specific test conditions.

1.2.24 Bottom Sediment and Water Content (Observed Measurement)

This is a measure of basic sediment and water absorbed and contaminating full-range crude and other hydrocarbon fractions.

1.2.25 Copper Number (Observed Measurement)

This is the amount (milligrams) of mercaptan sulfur in 100 mL of oil sample. It is used to measure mercaptan content in a general petroleum fraction.

1.2.26 Doctor Test (Observed Measurement)

Sodium plumbite solution is used to measure mercaptan content in a gasoline stock.

1.3 Chemical Compositions of Petroleum Fractions

To grasp fully the relationship between performance and fuel properties, is essential to understand the chemical composition of the fuel. This is currently done at great difficulty and expense, but enough data exist that several generalizations can be formulated.

1.3.1 Broad Component Classification of Hydrocarbons\(^{(41,56,59,68)}\)

Petroleum and coal-based liquid hydrocarbons contain chemical species from a list of over 1600 pure hydrocarbons and several related compounds. Nearly every crude oil has 300–800 measurable species at some detectable level. Among the categories are the following:

1. Paraffins (alkanes)
   - Straight chain (normal)
   - Branched chain (iso)

* The TBP ranges of the crude are not always complete. Very often, the assay is reported only to the last tangible cut range above the tower resid. This may be diesel, or more likely gas-oil material. Measuring the resid properties often seemed superfluous and unnecessary. Obtaining accurate temperatures and recovery percentages is also very difficult for temperatures much above 800 °F and certainly for those above 1000 °F. Many petroleums have estimated end-points between 1300 and 2000 °F.

In general, petroleum fractions are made of combinations of the above components in MW structures ranging from 2 to >600. Tables 2–4 present type and characterization breakdowns of various crude oils and their typical refinery cut fractions.

1.3.2 Crude Oil Analysis by Fractional Product Content\(^{(1–18,34,57,72)}\)

Crude oil distillation separates the basic components of petroleum into various streams, mostly on the basis of boiling point. Gasolines, kerosines, diesel, gas-oils, resids, etc. are all standard refinery terminology for some of these cuts. Refer to the glossary if a more detailed explanation is necessary.

A typical crude oil can be described compositionally in several ways:

- A typical crude oil composition specified by pure boiling range cut fractions is presented in Figure 1.
- Relative amounts of hydrocarbon types in a crude oil are displayed in Figure 2.
- A textual listing of a typical crude fraction assay is presented in Table 4.
- A graphical display of the boiling point curve typical of crude assay is shown in Figure 3.
- The delineation of various products based on TBP value is demonstrated in Figure 4.
Typically the TBP curve and a few of the important physical properties (viscosity, density, cloud and PPs, etc.) of each cut fraction are reported in a standard abbreviated laboratory analysis of a crude. More recently, a generic speciation by carbon number and type (PONA) is routinely reported if the proper spectrophotometric equipment and analyst knowledge are available.

1.3.3 Chemical Analysis of Refinery Products\(^{(47, 59, 62)}\)

Refinery products are divided into two categories, namely are “virgin” or “straight-run” streams that are derived from pure physical separation from the crude feed, and converted stocks which have been run through one or more thermal or catalytic reactions. Of the conversion reactions, cracking of large molecules into smaller ones is the most common. This category can be subclassified into thermally cracked stocks, catalytically cracked stocks and hydrocracked stocks. Other reactions common in refineries are reforming, isomerization and alkylation.

The major refinery streams of ultimate value in a refinery are virgin naphtha, thermal crackate, catalytic reformate and hydroprocessed stocks.

Compositional comparison charts are illustrated as follows:

- Figure 2 shows typical components in virgin crude cuts.
- Figure 5 shows typical component compositions for a catalytically reformed stock.
- Figure 6 shows typical component compositions for a catalytically cracked stock.
- Figure 7 shows typical component compositions for a hydrocracked stock.

Catalytic reformate contains the largest amount of aromatics, which increase the octane rating. Thermal crackate made from thermal cracking or coking processes contains significant amounts of olefins which are not stable and thus not suitable as a gasoline component. Virgin naphtha (straight-run naphtha) contains small amounts of aromatics but significant amounts of paraffins.
Figure 1 Sample crude oil composition.

Figure 2 Relative amounts of hydrocarbons in a crude oil.
1.3.4 Chemical Analysis of Synfuel Products \(^{57,72,73,142}\)

Most work on hydrocarbons has gone into products derived from crude oil refineries. There is, however, a significant base of stocks derived from shale oil, coal and heavy oil/tar sands recovery processes.

These stocks contain most of the same chemical components as do petroleum-based derivatives but will also contain substantial amounts of several biaromatic multi-ringed components that are not generally major components of the petroleum-based stocks. They tend to have higher nitrogen levels than most crudes and perhaps a slightly lower sulfur content. A partial listing of some of these chemicals is presented in Table 5.

1.3.5 Component Effects on Refinery Products

1.3.5.1 Motor Gasolines

Volatility characteristics for motor performance are dependent upon the amount of lighter components such as butane and pentane. Antiknock characteristics are highly dependent upon the components of the stock involved, especially in the \(C_6 - C_9\) range.

1. Paraffins: octane number increases with increasing MW and branchedness.
2. Olefins: octane number is better than that of corresponding (same carbon number) paraffins.
3. Naphthenes: have moderate octane numbers.
4. Aromatics: have excellent octane numbers but poor volatility and have some toxic characteristics that have resulted in some regulatory constraints on their usage levels in transportation fuels.

1.3.5.2 Other Petroleum Stocks

A lowering of aromatic content generally increases (improves) the SP.

The paraffin content correlates with FRP, CP and PPs of several fuel stocks. Lowering the amounts of paraffins and especially isoparaffins generally improves (lowers) these three property values.

The higher the Watson \(K\) factor, the higher is the paraffinicity; the lower the Watson \(K\) factor, the higher is the aromatics content.

Highly paraffinic crude oils may deposit waxes in transport lines and processing equipment. On the other hand, the lube oils made from these stocks are generally of superior quality.

Highly aromatic or naphthenic stocks will tend to form more coke in cracking and pyrolysis operations. They may also tend to foul catalyst pellet matrixes in various conversion processing operations.

Table 6 shows a series of gasoline blend components and a select set of their corresponding properties.

2 HYDROCARBON CHARACTERIZATION FROM DISTILLATION CURVES

2.1 Introduction

Hydrocarbon fractions, being a mix of several dozen to hundreds of hydrocarbon compounds, cannot be treated simply as a single pure component. A measure of the various molecular sizes is necessary in order to obtain meaningful thermodynamic information about the cut. The typical measure of molecular size distribution is via a volumetric distillation designed to measure the “true” molar boiling point of each incremental volume of overhead batch distillate. These boiling points, combined with corresponding cut point gravities, are used to estimate MWs. Nearly all industrial hydrocarbon characterization procedures require at least two of these quantities.

One more reason why this makes sense is that hydrocarbon cuts are usually separated in the refinery on the basis of distillation column performance. The boiling point range of a cut is highly dependent upon the size of the molecules, as are the subsequent properties of the fraction stream. Since the boiling point of each familiar homolog of components rises in a predictable fashion with size (i.e. MW), the boiling temperature of a cut indicates something about the relative size of the molecules in the
cut and their subsequent expected behavior. Typically, the hundreds of component species in a cut are “lumped together” on the basis of comparable boiling points for simplicity. This is why establishing the average “true” boiling point of a cut/fraction is so important. One can also then understand that the smaller the cut range, the more likely one is to be able to use these boiling-point lumping models (also called pseudocomponents or hypotheticals) with any reasonable accuracy.

There are numerous ways of using distillation curves to characterize hydrocarbon fractions. No particular purpose would be served by attempting to present all these methods here. Instead, only those considered most reliable and useful will be included.

2.2 Generation of Distillation Curves

There are four primary types of laboratory distillation curves that are used to characterize crude oils and refinery products, and these curves constitute the most important and useful information upon which the process design engineer must rely. Of these, the most useful curve is the true boiling point (TBP) curve. TBP values are rarely a final product specification but these values are most useful in extrapolating properties of various cuts within the measured TBP cut range.

1. The TBP distillation is basically a batch distillation conducted in equipment of high fractionation efficiency, such that each increment of overhead vapor is (theoretically) a pure component at its TBP. The curve is a plot of overhead temperature versus cumulative volume percentage overhead yield. A sample TBP–volume % overhead curve for a full range crude is shown in Figure 3.

One consistency problem here is the lack of a real standard procedure for conducting a TBP test. ASTM D-2892 is a standard that is often used, but most laboratories modify it for various reasons. Since the various laboratory stills in use employ
The terms “Oldershaw”, “Podbielniak”, “Hypercal” and “15/5” (15 trays, 5:1 reflux ratio) refer to distillations that are essentially TBP runs. The United States Bureau of Mines (USBM) historically used the “Hempel” distillation for its crude assay work. The Hempel distillation, and the very similar ASTM D-285, are what may be termed semifractionating distillations. Both of these procedures give some degree of fractionation, but are less efficient than a TBP distillation and should not be regarded as truly equivalent to TBP runs.

3. The first of these ASTM distillations is covered by ASTM specification D-86 for tests conducted at atmospheric pressure (ATM) for lighter refinery fuel-blend stocks (naphtha, kerosine, light diesel). D-86 values are often a final product specification.

4. The second major ASTM distillation is covered by ASTM specification D-1160 for tests conducted at high vacuum for heavier refinery high-boiling point stocks (heavy diesel, gas-oils, resid, etc.). D-1160 values are often a final product specification.

1000°F boiling points and below, they are quick and reliable. ASTM D-2887 and D-3710 are rapidly becoming laboratory standards. Whenever possible, the source of any directly measured TBP distillations should be at least one of the 15/5 or better procedures or the equivalent GC predictive method.

In some cases, the TBP curve is a derived function from one of two ASTM distillation procedures.

2.3 Cut Fraction Characterization – Manual Methods

2.3.1 Establishing the True Boiling Point Curve – Methods

The typical means of measuring molecular size distribution is with a volumetric TBP distillation. This is a laboratory-based batch distillation whereby the overhead recovery of a percentage of the initial charge is recorded versus the average temperature of the bottoms in the still pot. The following methods are used in industry today.

2.3.1.1 Distillation via American Society for Testing and Materials D-86 Procedures (Usually at 760 mmHg Pressure) This procedure is used for lower boiling hydrocarbon cuts such as gasoline, kerosines and even some light diesel oils. This test is a batch distillation in which no vapor fractionation occurs, so the still vapor temperature is theoretically the dewpoint of a continuously changing (increasing in MW and therefore boiling point) hydrocarbon stream. Although not directly related to composition, this test is still a primary test because of its low cost and high degree of standardization and reproducibility. Nearly all fuel product specifications are expressed in terms of a D-86.

2.3.1.2 Distillation via American Society for Testing and Materials D-1160 Procedures (Usually at 10 mmHg Pressure) This procedure is used primarily for higher boiling hydrocarbon cuts such as heavy oils, resids, fractionator bottoms, etc. The typical vacuum conditions provide a pressure at which a significant recovery of material can be obtained without the need to use high temperatures to vaporize. Hydrocarbons start cracking around 316–343 °C (600–650 °F), so the longer the analyst can carry out the distillation under lower temperatures, the more accurate the analysis of the heavy ends in the initial still charge will be.

This test is a batch distillation in which no vapor fractionation occurs, so the still vapor temperature is theoretically the dewpoint of a continuously changing (increasing in MW and therefore boiling point) hydrocarbon stream. Although not directly related to composition, this test is still a primary test because of its high degree of standardization and reproducibility. Nearly all heavy product specifications are expressed in terms of a D-1160.

2.3.1.3 Distillation via Experimental True Boiling Point Procedures TBP distillation is meant to represent the “true” molar boiling point of each incremental amount of recovered overhead still product, i.e. if each small amount of distillate liquid were in fact a pure component, its NBP would correspond to the still pot temperature at the time it went overhead. In practice, this cannot occur, but by increasing the fractionation efficiency of the still, the MW distribution of the overhead liquid can be narrowed. In this way, a fairly good estimate of the “average” molar boiling point of a distillate cut at a given temperature can be made. The still efficiency is dependent on the number of rectifying plates and the amount of reflux that is used to maintain liquid traffic in the trayed section. Typical TBP columns (Oldershaw and some of the newer systems) use what is known as a 15/5 specification, that is 15 trays with a 5:1 reflux ratio. This standard, however, is more traditional than anything, and most TBP cuts are taken under conditions ranging from 5/3 to 60/20, depending upon the equipment and the care taken by the laboratory analyst.

ASTM D-2892 is as close as anything to a standard for this test. It is prescribed only for a full-range crude analysis but should work well for any wide-boiling cut.

2.3.1.4 Distillation via American Society for Testing and Materials D-2887/D-3710 Gas Chromatography Procedures These are newer procedures, based on a GC reconstruction of the boiling point curve, which are quickly becoming the preferred reporting methods for literature and operations data. They are quick and accurate, although the required equipment is somewhat expensive. ASTM procedure D-3710 covers the analysis of stocks with NBP <260 °C (500 °F). D-2887 theoretically covers a full-range crude but must typically be limited to NBP <538 °C (1000 °F). Any molecules that are too large are either cracked in the elution column or end up as coke on the column packing.

D-2887 results are often close enough to “true” TBP that some laboratories will substitute them directly. Several correlations exist, however, for converting D-2887 values to “true” TBP and D-86 assays, and should be used preferentially.

Data concerning any hydrocarbon fraction will ultimately be obtained in one of the above forms. Occasionally, the curve for mid-range cuts will be reported as a composite, the lower boiling cuts being measured via the D-86 procedure and the higher boiling cuts being reported as D-1160. This protocol is fine as long as the assumptions are made clear in the reported data.

Several laboratory methods today combine a chromatography step with some form of additional downstream analysis of the eluate. Spectral emission is the most common supplemental analysis method, with gas chromatography/infrared (GC/IR) spectroscopy and gas chromatography/mass spectrometry (GC/MS) being the most advanced in terms of broad applicability. High-performance liquid chromatography (HPLC) with hydrodealkylation (HDA) is promising for determining aromatics in 343+ °C (650+ °F) fractions, but is limited for other components and boiling point ranges. This advanced equipment is also expensive and difficult for
all but trained laboratory operators to use. Therefore, its general usage will grow slowly for some time.

2.4 Establishing the True Boiling Point Curve – Where to Start

The normal method of petroleum fraction characterization requires the generation of a TBP curve. Unless measured directly, a fairly time-consuming and costly procedure, a TBP curve must be derived from another form of distillation.

Figure 3 shows typical relationships between an ASTM distillation curve and a TBP distillation curve for a full-range cut. The ASTM curve has had the 371 °C (700 °F) portion of the curve corrected to 760 mmHg pressure, because its data were taken at 10 mmHg via the D-1160 procedure, but the relationship of the resulting curve to the more tightly separated TBP curve is still valid. The equilibrium flash vaporization (EFV) curve shown on Figure 3 is an EFV curve of the type that used to be an industry standard method for estimating a single-stage ideal flash. With the availability of inexpensive computer software for stage flashes, this particular curve has fallen into general disuse and will not be covered here.

Several methods have evolved for relating the ASTM curves to a TBP curve. The classical graphical procedure based on both the Edmister–Pollock and Edmister–Okamoto methods is illustrated in Figure 8.

![Figure 8 ASTM–TBP relationships](image-url)
These methods are still recommended by the API and are used by refining engineers. Some use one method exclusively but the blend of the two seems to give the most uniform results. Most companies, and the API itself, have provided computer-compatible equations for distillation conversions based on Figure 8 or refinements thereof. A more detailed discussion of these procedures is covered in subsequent sections of this article.

Figure 9 shows the “preferred” methodology of the API Technical Data Committee as the solid lines and the author’s suggested deviations as the dashed lines. These procedures provide reasonable and consistent answers.

2.5 Quality of Data

The major problem in defining a TBP curve is not so much the manipulation of the data but rather the quality of the data themselves. ASTM distillations are defined by fairly rigid standards and as long as the equipment meets the standard and is run properly (most new analytical units are digitally controlled), the main source of error is the care with which the analyst reports the data. The quality of directly reported TBP curves, however, has error inherent from both the distillation conditions and the method of analysis, in addition to the biases and errors of the analyst.

Since the generation of “boiling-lumped” pseudocomponents requires a TBP curve, the real problem becomes one of defining the curve from the “best-quality” data. A good analyst with good equipment, generating a “true” TBP curve, is the optimum situation. The word “true” is in quotes because sometimes reported TBP values are actually ASTM distillations that have been transformed by either the analyst or the apparatus (the newer ones under microchip control). Use of these latter TBP values leaves one at the mercy of the transform method. Any such transformed data should be thoroughly rechecked before use.

Given the existence of a real or assumed TBP curve, the engineer then starts to divide the curve into volume-specific cuts defined by their corresponding segmental end-point temperature. Figure 12(a) and (b) (see later) shows how this might be done.

In any case, the reader must realize that converting from one distillation curve to another is somewhat of an inexact procedure, and errors as great as 17–22° from one distillation curve to another is somewhat of a reality. Figure 12(a) and (b) (see later) shows how this might be done.

2.6 Methods to Use When Lacking “Total Data”

The above recommendations are dependent upon the existence of some real distillation data on the hydrocarbon cuts in question. When such data are not available, the engineer must use judgment and some knowledge about the relative amounts of the various types of components in the stream.

For estimating an ATM tower resid, one may have only a sample of the full-range crude and an idea of the fractional residual. Knowing that most resids (at least those from reasonably efficient fractionation systems) have TBPs starting around 260–288°C (500–550°F), one may elect simply to cut off the resid tail of the “full-range TBP” at the volume percentage corresponding to the fraction residual and use that as the heavy fraction TBP curve, normalizing the cut fractions to a full 100% basis.

An extension of this line of thinking allows one to specify a full-range cut based on some assumptions about the various parts of that whole stream. One might characterize the effluent of a hydrocracker as consisting of 20 standard vol.-% of light naphtha cuts [32°C (90°F) < NBP < 82°C (180°F)], 30% heavy naphtha cuts [82°C (180°F) < NBP < 196°C (385°F)], 40%
of mid-distillate cuts [$196^\circ\text{C} (385^\circ\text{F}) < \text{NBP} < 287^\circ\text{C} (550^\circ\text{F})]$ and the residual.

From these assumptions, a TBP curve for the full cut can be estimated. Although not as accurate as distillation curve analysis, this method will allow the engineer to proceed with work in the absence of “real” data.

Typical procedures, assuming the availability of some TBP data, are illustrated in Table 7.

In 1987, the American Petroleum Institute (API) also developed a correlation for interconversion of D-2887 and TBP data. The original intent was to develop the correlation at each “standard” volume node (10, 30, 50, 70, 90% points).

In general, the correlation did well except for several diesel–gas-oil range boiling cuts that had a fairly “flat” boiling range from the 30–70% range. In such cases, the correlation predicted regressive values of at least one of the 50, 70 or 90% points. This did not go over well in the refining community and the correlation was revised to its current form; see sections 3.12.2.1 and 3.12.2.2 for descriptions. In spite of the problems, it is still an excellent method of predicting TBPs from a very limited amount of data. If one has only 10, 50 and 90% D-86 values (not an uncommon situation), this method may give better results than using interpolations to calculate difference values.

If one must interpolate from data not on the “standard” reporting volumes nodes, use a quadratic or spline fit procedure. To extrapolate (very carefully – avoid if at all possible!), use a probability plot format. The MWs, and thus the boiling points, of the stream components can be assumed to be normally distributed about a mean value.

### 2.7 Establishing the Pseudocomponents

Whereas arrival at a “final” TBP curve may be accomplished in several ways, the method of defining pseudocomponents (or commonly called hypotheticals) has less variation.

Petroleum fraction pseudocomponents are traditionally defined in terms of their NBPs. In the simplest method of determination, a certain boiling range of a TBP curve is segregated and the mid-volume boiling temperature is found graphically. In looking at Figure 4, one might define nine pseudocomponents by the heavy cut lines crossing the TBP curve. The components would then be identified as NBP140, NBP316, NBP413, NBP490, NCP557, NBP621, NBP697, NBP794 and finally, NBP1000, as in Figure 4. One could rename them to corresponding Celsius, Kelvin or any other meaningful scale for tracking purposes.

This last mid-range temperature is estimated from an assumed end-point for the heavy end of the curve. It is most difficult to measure the boiling points of heavy resids, as they tend to be destroyed (cracked) in the process of having their boiling point measured. Unfortunately, this lack of a definable end-point is a major source of error in the characterization of resid fractions. One can use some advanced interpolation methods (details of which are beyond the scope of this article) to aid in end-point estimates, but even these are only of marginal value. It should also be noted that MW correlations based on NBP and gravity become increasingly inaccurate for higher boiling point material.

Using the classical TBP cut method of determining pseudocomponents has its limitations in heavy resid processing.

### 2.8 Calculation of the Average Cut Parameters

Once the TBP range for the pseudocomponent has been defined, the calculation of MW and related parameters can commence. Nearly all correlations require the NBP and specific gravity (SG) of a cut. Some use these two parameters completely separately and some incorporate the SG in a Watson $K$ ($K_W$) parameter. Implicit with any TBP curve is a related gravity versus volume fraction curve or a gravity–boiling point curve.
In general, the SG of the overhead product increases as the distillation progresses (i.e. as both volume-% and/or distillation temperature increase). In many instances, the SG curve is reported along with the temperature curve. This is the ideal situation, in that all quantities necessary to define the MW are specified.

Usually just the average whole-stream gravity is reported. In this case, the best procedure is to estimate the individual pseudocut gravities based on some idea of what the SG of the cut does with increasing NBP. Figure 10 shows a typical representation of a straight-run cut SG–volume-% curve and one of a “cracked” fraction. Both are monotonic, with a constantly increasing dependent function value. The cracked fraction, however, has an inflection point (where the second derivative changes).

Figure 11 shows a typical representation of cut fraction $K_W$–vol.% curves for several different hydrocarbon stream types. The characteristic of most interest to refiners is the fact that for thermally cracked and hydrocracker effluents, the $K_W$ of the mid-distillate material tends to be low in comparison with the tails. The explanation for this is fairly simple. $K_W$ is strongly correlated with the degree of paraffinicity and inversely correlated with the degree of aromaticity in a fraction. Most hydrocracking forms paraffinic products, highly saturated although often highly branched. The hydrocracking process and reforming processes also produce a large number of single-ring aromatic compounds with boiling points in the region of kerosine and light diesel with a corresponding reduction in average $K_W$ in this area. In most straight-run fractions, by contrast, the lightest components tend to be paraffinic and the heavy components are more aromatic and naphthenic, giving a continually decreasing $K_W$ vs volume percentage curve.

Defining cut gravity in the absence of real data depends chiefly upon how the variation of the $K_W$ is perceived. For straight-run crudes, the assumption of a constant $K_W$, based on either the cut-point TBP (preferred by most of the industry) or ASTM-D-2887 mid-point temperature, is the usual method. The engineer, however, knowing something about the true $K_W$ curve, may want to make some educated guesses about the local variations from this assumption.

A few comments should be made with respect to Figure 11. The curves are typical for shape only. Actual plot values are dependent upon the stream and can vary greatly from those shown. Within whole crude cut fractions, constant $K_W$ is not a bad assumption, especially for straight-run fractions. For hydrocracked cuts, it may be invalid since aromatics accumulation from the conversion process tends to build up in the middle distillate range. Crude light straight run (LSR) tend to be more paraffinic on average than the whole crude. This generalization also holds for full-range hydrocracker effluents. Highly paraffinic crudes also have a region of increasing $K_W$ but it tends to start with 650°F+ NBP material and the change is not as pronounced as with the mid-range hydrocracker effluents. In the case of hydrocracker effluents, the double-inflected curve in Figure 11 may be a more appropriate type to follow.

### 2.9 Measures of “True” Boiling Point

Once the NBP and SG of a cut have been set, the MW can be obtained in a straightforward fashion. Details of the best current methods of calculating hydrocarbon cut fraction MWs are discussed in section 3 and will not
be repeated in any great detail here. What is of some controversy is just what the NBP measures. In any cut, there are several measures of a mean boiling temperature.

There is the volumetric average boiling point (VABP), which is not identical with the mid-boiling point temperature (see Figure 12a and b), the CAPB, which is the theoretical basis for \( K_W \) calculations, the MABP (defined in Figure 12a and b) and the MEABP, which the API defines as the average of the CAPB and the MABP. These values are outlined graphically in Figure 12(a) and (b) and explained as numerical approximations below.

Several methods typically used by oil companies and process engineering contractors use the VABP, a very simple number to generate or estimate. The Twu(142) correlation used in some process simulation packages such as “Process/Provision” uses MABP, and the most recent correlation approved by the API Technical Data Committee uses MEABP, as did earlier versions of their methodology.

Note that for narrowly defined TBP temperature cuts, all these measures of “average” boiling point tend to converge. It is only when trying to characterize a wide-boiling fraction that the differences in the NBP values become significant. An exception is in the use of mid-range boiling points for the front and back ends of a cut (i.e. the 0–10 and 90–100% ranges). The mid-range value in these cases can be significantly lower than the VABP (5% vs 7% on a steeply sloped curve). An extra effort should be made to define the VABP better for these tail cuts.

The five primary boiling point vectors can be estimated by algebraic means, given a defined mixture. The temperature units of the first three distillation data functions do not matter as long as they are consistent with each other. MEABP is typically considered to be the best approximation for the NBP of a cut and, if available, is the temperature of preference. For narrow cuts, however, all of the values should converge within a few degrees of each other.

Given the fact that full-range analyses of crudes and fractions of crudes are time-consuming and costly, the API has developed the following correlations for a broad boiling range hydrocarbon.

From D-86 distillation data, find the VABP with five standard cut values (Equation 10):

\[
VABP = \frac{T_{10} + T_{30} + T_{50} + T_{70} + T_{90}}{5}
\]  

(10)

If data are scarce and a calculation has to be made, one could use (as have some) Equation (11):

\[
VABP = \frac{T_{10} + T_{50} + T_{90}}{3}
\]

(11)

The author feels, however, that it would be better to intuitively estimate a \( T_{30} \) and a \( T_{70} \), then use Equation (10).

The VABP and subsequent “average” derivation methods can also be used with TBP curves, provided that they are identified as such, and that a corresponding D-86 vector has been established corresponding to the TBP curve. Often the D-86 and TBP distillation averages are used interchangeably (and improperly) by novices. The primary reason why the D-86 values need be present is for calculating 10–90% slopes (Equation 12):

\[
SL_{1090} = \frac{T_{90} - T_{10}}{90 - 10}
\]

(12)

The other assay average parameters are calculated according to Equations (13–24):

\[
WAPB = VABP + Temp\_diff\_wt
\]

(13)
Figure 12 Determination of (a) volume average NBP and (b) molar average NBP. The Watson \( K \) uses the cubic average boiling point, \( \text{CABP} = \sqrt[3]{\text{VABP}^3 \, dV} \). Most MW correlations use the molar average boiling point, \( \text{MABP} \). 1988/91 API revised correlations use the mean average boiling point, \( \text{MEABP} \), which is the average of the cubic and molar average boiling points, \( \text{MEABP} = (\text{CABP} + \text{MABP})/2 \).
Figure 13 (a) Boiling point conversion chart; (b) Watson $K (K_W)$ correction for (a). Note the logarithmic abscissa in (b).\textsuperscript{(9,97)}
where Temp_diff_wt is determined by Equation (14):

\[
\ln(\text{Temp}_\text{diff}_\text{wt}) = -3.062 - 0.01829(\text{VABP} - 32)^{0.6667} + 4.458S_{100}\text{F}^{0.25} \text{ (units of } ^\circ\text{F})
\]  

(14)

where Temp_diff_mo is determined by Equation (17):

\[
\ln(\text{Temp}_\text{diff}_\text{mo}) = -0.5638 - 0.007981(\text{VABP} - 32)^{0.6667} + 3.047S_{100}\text{F}^{0.3334} \text{ (units of } ^\circ\text{F})
\]  

(17)

\[\text{MABP} = \text{VABP} - \text{Temp}_\text{diff}_\text{mo}\]  

(16)

where Temp_diff_cu is determined by Equation (20):

\[
\ln(\text{Temp}_\text{diff}_\text{cu}) = -0.2359 - 0.0691(\text{VABP} - 32)^{0.45} + 1.886S_{100}\text{F}^{0.45} \text{ (units of } ^\circ\text{F})
\]  

(20)

\[\text{MEABP} = \text{VABP} - \text{Temp}_\text{diff}_\text{nbp}\]  

(22)

where Temp_diff_nbp is determined by Equation (23):

\[
\ln(\text{Temp}_\text{diff}_\text{nbp}) = -0.9440 - 0.00865(\text{VABP} - 32)^{0.6667} + 2.998S_{100}\text{F}^{0.3334} \text{ (units of } ^\circ\text{F})
\]  

(23)

\[
\ln(\text{Temp}_\text{diff}_\text{nbp}) = -1.532 - 0.0128(\text{VABP})^{0.6667} + 3.617S_{100}\text{F}^{0.3334} \text{ (units of } ^\circ\text{C})
\]  

(24)

Table 8 shows a comparison of these boiling point averages of four different cuts at different VABPs.\(^{157}\)

### 2.10 Measures of Fractionation Efficiency

Distillation assays can have value within themselves. Fractionation performance in crude units and other refinery fractionators is commonly specified as a targeted distillation value to be achieved, such as a D-2887 (90%) value maximum for CARB (California Air Resources Board) gasoline, though this latter method is more often used to set draw rates. A pure measure of column fractionating capacity is often gaged as the difference between the ASTM 5% point of a product and the ASTM 95% point of the next lighter product. This “gap” is defined according to Equation (25):

\[
\text{gap} = \text{heavy curve D86}_{5\%} - \text{lighter curve D86}_{95\%}
\]  

(25)

A high degree of fractionation will result in the 5% point being higher than the 95% point, producing a so-called positive “gap” value. Poor fractionation, on the other hand, will result in an overlap where the 95% point is actually higher than the 5% point, or a negative “gap”. The required fractionation performance is generally specified by the process engineer and is generally higher for the lighter product cuts unless the column has some mechanical problems.

Gaps of 17–28°C (30–50°F) are commonly found between naphtha (gasoline) cuts and kerosine or between kerosine and light diesel. Gaps of 0 to −11°C (0 to −20°F) are more common between heavier cuts. Figure 14(a–c) illustrates this situation for a full-range crude.

Note that if the fractionation is perfect, the TBP curves of the cuts form a complete unbroken curve that is identical with the TBP curve of the fractionator feed. Perfect fractionation, however, is never achieved in commercial side-draw columns. Some of the heavier product is unavoidably withdrawn with the lighter product and vice versa, thus forming the “tails” shown in Figure 14(b). The poorer the degree of fractionation, the greater will be the deviations of the TBP tails from the feed TBP curve, and consequently the greater will

2.11 Interconversion of Distillation Data

2.11.1 Introduction

The general use of the TBP (and other) distillation curves as part of the characterization process for cut analyses has been covered to this point. The major focus of this section is to enable the chemist or engineer to arrive at an ATM TBP curve for a stock, particularly from data that were derived from an ASTM standard test. From these data, several other curves and physical properties can be estimated with good accuracy. Very often, these methods can be used (usually with some mathematical manipulation) to impute various inspection data in hydrocarbon streams.

The most important thing to realize is that converting from one distillation curve to another is a rather inexact procedure. Errors as great as 17–22 °C (30–40 °F)
may occur with wide-boiling stocks. It is essential, therefore, that the engineer be realistic about the accuracy of estimated distillation curves. This means checking important results by more than one method, and allowing reasonable safety margins so that the overall workability of a design or analysis dependent upon this data is not jeopardized by unavoidable inaccuracies in the correlations.

Several methods for converting one distillation curve to another are presented in this section. Most are currently recommended by the API Technical Data Committee, the premier nonconfidential information source currently available for hydrocarbon stock thermodynamics. A few are useful correlations that the author has used for this type of work.

In general, for converting an ASTM curve to a TBP curve (or vice versa), Edmister’s methods (as shown in Figure 8) and its recent empirical derivatives are generally recommended.

The classical correlation for 50% point ASTM vs TBP is based on work by Edmister and Pollack in 1948 and is considered by the API to be superior to a later correlation published by Edmister and Okamoto in 1958. In using Figure 8, the 50% point temperature of the required curve is determined from the 50% point of the known curve. A recent API correlation for this graphical method has been published, where the 10, 30, 50, 70, 90 and 95 vol.-% points are known on one or the other side. This method is probably the most accurate available procedure, assuming that one has enough data.

Since most refineries and petrochemical plants try to get by with the minimum amount of expensive on-line analyzers, these methods are well tested.

In a few cases, an analyzer will only report one or two specific volume-% points. Sometimes the residual portions of the distillation curve cannot be obtained. For these situations, one can use an older API correlation based on inter-conversion from one corresponding volume-% directly to that of the target curve, without assuming knowledge of the rest of the source or target value curves. There are some caveats that the user must observe. Trying to construct a full-range curve from the point method can lead to problems, which will be described in detail below. If one is able to generate reliably a full-range ASTM or TBP distillation, the full-range methods should be used.

In any event, this correlation has been useful to the author and can be utilized as a check on the values derived from the other methods.

### 2.11.2 Physical Distillation Conversion Procedures

The most recent revisions of the API Technical Data Book (1987–98) contain several useful procedures for interconversion of “standard” mixed-hydrocarbon distillation curves.

Figure 9 (solid lines) shows the 1994 API recommended conversion pathways for constructing one curve type from another. An explanation of these procedures, or their acceptable alternatives (dashed lines), follows.

#### 2.11.2.1 Interconversion of American Society for Testing and Materials D-86 and True Boiling Point Distillation Curve at Atmospheric Pressure Full Range Assay

This method should be used only for a fully defined assay of a stream. Trying to derive a full TBP curve from three or more such point applications of this method can create problems.

Equations (26) and (27) are used to interconvert ASTM D-86 and ATM TBP distillation data:

\[
\text{TBP}_{50\%} = a(\text{ASTM D-86}_{50\%})^b \tag{26}
\]

\[
\text{ASTM D-86}_{50\%} = \left(\frac{TBP}{a}\right)^{1/b} \tag{27}
\]

where \( a = 0.8718 \) and \( b = 1.026 \) for the interconversion of the 50% points, TBP temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled, in degrees Rankine, and ASTM D-86 = observed ASTM D-86 temperatures at the corresponding volume-% distilled, in degrees Rankine.

The procedure works by calculating differential temperatures from the mid-volume boiling point value and translating that value to the other corresponding member of the pairing.

The difference between adjacent cut points can be determined from a series of equations for each interval (Equation 28):

\[
\text{TBP}_{\text{diff}}(I) = C_0(\text{D-86}_{\text{diff}})^{C_1} \tag{28}
\]

where \( C_0 \) and \( C_1 \) are coefficients for varying temperature ranges, \( \text{TBP}_{\text{diff}}(\ ) \) and \( \text{D-86}_{\text{diff}}(\ ) \). Their vectors are shown in Table 9. Temperature values and differences must be in consistent units.

To determine the TBP values at any percentage distilled, add or subtract the proper differentials from

\]

To determine calculated ASTM D-86 values from measured TBP values, reverse the procedure.

### 2.11.2.2 Interconversion of American Society for Testing and Materials D-86 and True Boiling Point Distillation Curve at Atmospheric Pressure with Only Three or Fewer Points

This method should be used only for point-to-point conversions when no better range of data is available. Trying to derive a full TBP curve from three or more such point applications of this method can create problems. Distillation curves, by definition, are monotonic functions increasing with temperature. In some cases one sees a fairly flat mid-range curve (little temperature increase between the ranges of, for example, 30–40 and 60–70% – a common occurrence with many hydropyrocracked stocks and some resid/bottoms streams. These correlations have yielded, on occasion, a distillation curve with the 50 or 70% points equal to or below the corresponding 30% or 50% values. This, of course, is not acceptable. Use this correlation with some care.

Equations (35) and (36) cover point-to-point interconversion of ASTM D-86 and ATM TBP distillation data:

\[
\text{TBP} = a(\text{ASTM D-86})^b \tag{35}
\]

\[
\text{ASTM D-86} = \left(\frac{\text{TBP}}{a}\right)^{1/b} \tag{36}
\]

where \(a\) and \(b\) are constants varying with the percentage of liquid sample distilled as given in Table 10.

### 2.11.2.3 Interconversion of American Society for Testing and Materials D-1160 Data and True Boiling Point (10 mmHg) Data

D-1160 is a common ASTM procedure for distilling heavy stocks whose final boiling temperatures at ATM pressure are well above the cracking initiation temperatures of 316–343 °C (600–650 °F). The presence of a significant amount of cracked products in the outflow of the unit will skew the curve erroneously. A 10 mmHg pressure in the still will safely allow the analysis of stocks that ordinarily could not be measured with ATM equipment. The methodology here is based on API Technical Data Book Procedure 3A2.1, which is the classical Edmister–Okamoto method. Figure 15 is a graphical representation of this method.

The \(T(50), T(70), T(90)\) and \(T(\text{EP})\) of the TBP 10 mmHg and D-1160 curves are assumed to be identical by convention. No interconversion is necessary for them.

**Warnings/caveats.** Many people make the mistake of assuming that the \(T(50), T(70), T(90)\) and \(T(\text{EP})\) of the TBP 760 mmHg curve and D-1160 curves are identical by convention. Pressure interconversion

* TBP: TBP temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled are in degrees Rankine. ASTM D-86: observed ASTM D-86 temperatures at corresponding volume percentage distilled, in degrees Rankine.

![Figure 15](image-url)
between curve types must be done for corresponding cuts at identical pressures. Pressure corrections can be routinely applied before or after the fact to initial data or derived intermediate values, to yield the final curve. The procedure for this is as follows:

1. Calculate the D-1160 $T(30)$ to $T(50)$ difference (units of °F): Given (Equation 37)

$$TBP_{diff}(1) = TBP_{10}(50) - TBP_{10}(30)$$ (37)

then (Equation 38)

$$D-1160_{diff}(1) = D-1160(50) - D-1160(30)$$

$$= -6.993 \times 10^{-2} + 1.354 TBP_{diff}(1)$$

$$- 2.481 \times 10^{-3} TBP_{diff}(1)^2$$

$$+ 5.894 \times 10^{-6} TBP_{diff}(1)^3$$

$$- 4.780 \times 10^{-9} TBP_{diff}(1)^4$$ (38)

2. Calculate the D-1160 $T(10)$ to $T(30)$ difference (units of °F): Given (Equation 39)

$$TBP_{diff}(2) = TBP_{10}(30) - TBP_{10}(10)$$ (39)

then (Equation 40)

$$D-1160_{diff}(2) = D-1160(30) - D-1160(10)$$

$$= -6.993 \times 10^{-2} + 1.354 TBP_{diff}(2)$$

$$- 2.481 \times 10^{-3} TBP_{diff}(2)^2$$

$$+ 5.894 \times 10^{-6} TBP_{diff}(2)^3$$

$$- 4.780 \times 10^{-9} TBP_{diff}(2)^4$$ (40)

3. Calculate the D-1160 $T(IP)$ to $T(10)$ difference (units of °F): Given (Equation 41)

$$TBP_{diff}(3) = TBP_{10}(10) - TBP_{10}(IP)$$ (41)

then (Equation 42)

$$D-1160_{diff}(3) = D-1160(10) - D-1160(IP)$$

$$= -3.896 \times 10^{-2} + 2.315 TBP_{diff}(3)$$

$$- 1.650 \times 10^{-3} TBP_{diff}(3)^2$$

$$+ 5.977 \times 10^{-6} TBP_{diff}(3)^3$$

$$- 4.735 \times 10^{-9} TBP_{diff}(3)^4$$ (42)

To determine the D-1160 values at any percentage (besides 50%) distilled, add or subtract the proper differentials from the predicted 50% D-1160 temperature (Equations 43–45) (the units in these equations must be consistent with one another):

$$D-1160_{0\%} = D-1160_{50\%} - D-1160_{diff}(1)$$

$$- D-1160_{diff}(2) - D-1160_{diff}(3)$$ (43)

$$D-1160_{10\%} = D-1160_{50\%} - D-1160_{diff}(1)$$

$$- D-1160_{diff}(2)$$ (44)

$$D-1160_{30\%} = D-1160_{50\%} - D-1160_{diff}(1)$$ (45)

2.11.2.4 Conversion of True Boiling Point Data to/from American Society for Testing and Materials D-1160 Data

1. Calculate the TBP $T(30\%)$ to $T(50\%)$ difference (units of °F): Given (Equation 46)

$$D-1160_{diff}(1) = D-1160(50\%) - D-1160(30\%)$$ (46)

then (Equation 47)

$$TBP_{diff}(1) = TBP_{10}(50\%) - TBP_{10}(30\%)$$

$$= 2.416 \times 10^{-1} + 6.940 D-1160_{diff}(1)$$

$$+ 1.813 \times 10^{-3} D-1160_{diff}(1)^2$$

$$- 3.299 \times 10^{-6} D-1160_{diff}(1)^3$$

$$+ 1.692 \times 10^{-9} D-1160_{diff}(1)^4$$ (47)

2. Calculate the TBP $T(10\%)$ to $T(30\%)$ difference (units of °F): Given (Equation 48)

$$D-1160_{diff}(2) = D-1160(50\%) - D-1160(30\%)$$ (48)

then (Equation 49)

$$TBP_{diff}(2) = TBP_{10}(30\%) - TBP_{10}(10\%)$$

$$= 2.416 \times 10^{-1} + 6.940 D-1160_{diff}(2)$$

$$+ 1.813 \times 10^{-3} D-1160_{diff}(2)^2$$

$$- 3.299 \times 10^{-6} D-1160_{diff}(2)^3$$

$$+ 1.692 \times 10^{-9} D-1160_{diff}(2)^4$$ (49)

3. Calculate the TBP $T(IP)$ to $T(10\%)$ difference (units of °F): Given (Equation 50)

$$D-1160_{diff}(3) = D-1160(10\%) - D-1160(IP)$$ (50)

then (Equation 51)

$$TBP_{diff}(3) = TBP_{10}(10\%) - TBP_{10}(IP)$$

$$= -7.314 \times 10^{-3} + 0.5368$$

$$\times D-1160_{diff}(2) - 2.899$$

$$\times 10^{-3} D-1160_{diff}(2)^2 + 5.452$$

$$\times 10^{-5} D-1160_{diff}(2)^3 - 9.622$$

$$\times 10^{-9} D-1160_{diff}(2)^4$$ (51)
The $T(50\%), T(70\%), T(90\%)$ and $T(\text{EP})$ of the TBP and D-1160 are assumed identical by convention. The units in Equations (52–54) must be consistent with one another.

$$\text{TBP}_{0\%} = \text{TBP}_{50\%} - \text{TBP}_{\text{diff}}(1)$$

$$- \text{TBP}_{\text{diff}}(2) - \text{TBP}_{\text{diff}}(3) \quad (52)$$

$$\text{TBP}_{10\%} = \text{TBP}_{50\%} - \text{TBP}_{\text{diff}}(1) - \text{TBP}_{\text{diff}}(2) \quad (53)$$

$$\text{TBP}_{30\%} = \text{TBP}_{50\%} - \text{TBP}_{\text{diff}}(1) \quad (54)$$

### 2.11.2.5 Correcting True Boiling Point to Atmospheric Pressure

The following method, based on the Maxwell–Bonnell\(^{(9)}\) boiling point conversion, API Procedure 3A4.1/Figure 5A19.1, is probably the most utilized correlation in refinery methods and data analysis. ATM boiling points are the starting point for so many correlations.

This method works well only for actual TBP data at any pressure or for ASTM D-1160 subatmospheric to 10 mmHg data. Some people will try to use it to correct ASTM distillations as well. It is not as accurate this way, although it may give reasonable results. For interconversions of other distillation types, one should use the conversion protocol of Figure 9, which forces the pressure calculation into the TBP realm.

The chart upon which this method is based is provided in equation form below.

### Distillation Pressure Interconversion – Numerical Method

For subatmospheric to atmospheric conversion, given a volume-%, a subatmospheric distillation temperature and a $K_W$ (either known or estimated), find the ATM cut point temperature via one of Equations (55–57):

Define

$$\log p^* = \frac{3000T^* - 6.762}{43T^* - 0.9877} \quad (55)$$

when $T^* > 0.0022$ ($p^* < 2 \text{ mmHg}$).

Define

$$\log p^* = \frac{2663T^* - 5.994}{95.76T^* - 0.9725} \quad (56)$$

when $0.0013 < T^* < 0.0022$ (2 mmHg $< p^* < 760 \text{ mmHg}$).

Define

$$\log p^* = \frac{2770T^* - 6.413}{36T^* - 0.9897} \quad (57)$$

when $T^* < 0.0013$ ($p^* = 760 \text{ mmHg}$).

In these equations, $p^*$ is vapor pressure (mmHg), $T^*$ is given by Equation (58):

$$T^* = \left( \frac{T_{b, \text{atmos}}} {T_{b, \text{non-atmos}}} \right) - 0.0002867(T_{b, \text{atmos}}) \quad (58)$$

$T_{b, \text{atmos}}$ = atmospheric cut-point temperature corrected to $K_W = 12$, in degrees Rankine, and $T_{b, \text{non-atmos}}$ = non-atmospheric cut-point temperature, in degrees Rankine.

The value of $T_{b, \text{atmos}}$, and therefore $T^*$, must be adjusted until $p^*$ equals the pressure conditions of the subatmospheric distillation being converted. The normalized (to $K_W = 12$) temperature is then converted back to the real $K_W$ basis using Equation (59):

$$DT = T_{b, \text{atmos}} - T_{b, \text{non-atmos}} = A(K_W - 12)$$

$$\times \left( \frac{\log p^*}{760 \text{ mmHg}} \right) \quad (59)$$

For $T_{b, \text{atmos}} > 400 ^\circ \text{F}$, $A = 2.5$.

For $T_{b, \text{atmos}} < 200 ^\circ \text{F}$, $A = 0.0$.

For $200 ^\circ \text{F} < T_{b, \text{atmos}} < 400 ^\circ \text{F}$,

$$A = 2.5\left(T_{b, \text{atmos}} - 200\right)/200$$

The API has recently proposed a revised correction factor that is similar in form and shown in Equation (60):

$$DT = T_{b, \text{atmos}} - T_{b, \text{non-atmos}} = B(K_W - 15)$$

$$\times \left( \frac{\log p^*}{760 \text{ mmHg}} \right) \quad (60)$$

For $200 ^\circ \text{F} < T_{b, \text{atmos}} < 600 ^\circ \text{F}$, $B = 3.85$.

For $T_{b, \text{atmos}} < 200 ^\circ \text{F}$, $B = 0.0$.

For $T_{b, \text{atmos}} > 800 ^\circ \text{F}$, $B = 14.9$.

For $600 ^\circ \text{F} < T_{b, \text{atmos}} < 800 ^\circ \text{F}$,

$$B = 3.85 + 11.02\left(T_{b, \text{atmos}} - 600\right)/200$$

This latter method using Equation (60) was developed specifically for full-range crude oils. The data from which it was taken were a series of specially assayed common crudes for sale on the world market. For narrower fractions, the Maxwell–Bonnell methods based on Equation (59) are preferable. The user may prefer his/her own plant data to recalibrate the coefficients used.

### 2.11.2.6 Correcting American Society for Testing and Materials D-86 for Cracking\(^{(13,14,75)}\)

The following procedure is the classical correction made to ASTM D-86 values in the high-temperature range [$>246 ^\circ \text{C}$ (475 ^\circ \text{F})] to adjust for the cracking of heavier molecules and thus a higher light ends yields than existed in the original sample. The value of this correction procedure has been hotly debated in the last 10 years. An equal number of refining companies can be found on both sides of the controversy – that cracking correction is useless or that it is indispensable. Both sides will claim that proprietary data in their possession prove their respective contentions. For the sake of completeness, it will be included here.

The procedure corresponds to Figure 2.B.1.1 of the API 1964 Technical Data Book\(^{(13)}\) (Equation 61). It was
officially removed from the 1987 version 4.\(^{10}\)

\[
\log[D-86_{\text{diff}}] = -1.587 + 0.00473T_{D-86}
\]

where \(D-86_{\text{diff}}\) is the correction that should be made to any \(D-86\) distillation value that exceeds 246 °C (475 °F) and \(T_{D-86}\) is the \(D-86\) value (°F) of concern.

2.11.2.7 Distillation Pressure Interconversion – Gas Chromatography Methods

The use of GC equipment is becoming a standard practice for laboratory and online analyses of hydrocarbon streams. What must be remembered is that the gas chromatograph will detect the size of the last and presumably largest molecules that elute through the chromatographic column.

The distillation procedures are based on manual observations by an analyst or an automated observation function that mimics an analyst. For this reason, determining the “final boiling point” is a tedious and inaccurate process. It is really difficult to determine the very bottoms of a cut; in fact, it is usually impossible. Absolute purity of the overhead is another issue. GC provides good separation but distillation often does not.

The GC end-point value is artificially skewed to the high end as opposed to what would be observed in a physical distillation. Therefore, the following protocol is proposed (Equation 62):

\[
D-2887_{\text{FBP}} = D-2887_{98.5\%}
\]  

Equation (62) is based on the author’s experiences with GC analyses and conversions. Using even interpolated values of the 98.5% recovery for the final boiling point is better than using the reported \(D-86\) end point.

2.11.2.8 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887/D-3710) to American Society for Testing and Materials D-86 Distillation – Method 1

Equation (63) is used to convert what is known as a simulated distillation (SD) in weight-percentage to an \(D-86\) distillation in volume-percentage. It is based on API Technical Data Book (1987) procedure 3A3.2.\(^{10}\) This method provides a one-to-one point correspondence from one distillation type to the other. If one has a full set of distillation data, the next procedure (section 2.12.2.9) may be a preferred method.

\[
D-86(\%) = a(\text{SD})^b F^c
\]

where \(D-86(\%)\) = observed ASTM D-86 temperatures at 0, 10, 30, 50, 70, 90 and 100 vol.-% points, in degrees Rankine, \(\text{SD}(\%)\) = \(D-2887\) temperatures at corresponding weight percentage points, in degrees Rankine. \(F\) = a variable parameter given by Equation (64):

\[
F = 0.009524(\text{SD}_{10\%})^{0.0437}(\text{SD}_{90\%})^{0.6147}
\]

\(SD_{10\%}\) is the simulated distillation temperature at the 10% point, in degrees Rankine, \(SD_{50\%}\) is the simulated distillation temperature at the 50% point, in degrees Rankine, and \(a, b, c\) = constants varying with the percentage of liquid sample distilled as given in Table 11.

A standard for SDs, or simdist as they are commonly referred to, is presented in ASTM D-2887 for full-range 0–1000 °F NBP cuts and in D-3710 which is a procedure for naphtha-based cuts at or below 260 °C (500 °F) NBP. Unfortunately, it is not simple to follow either standard completely to the letter and simdist values may have slightly more variation in their repeatability than is desirable. Use them with care.

2.11.2.9 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to American Society for Testing and Materials D-86 Distillation – Method 2

The methodology here is based on API Technical Data Book (1994) Procedure 3A3.1.\(^{9}\)

This method should be used only for a fully defined assay of a stream. Trying to derive a full TBP curve from three or more such point applications of this method can create problems.

Equations (65–66) are used to interconvert ASTM D-86 and ATM TBP distillation data:

\[
D-86_{50\%} = a(D-2887_{50\%})^b
\]

\[
D-86_{50\%} = \left(\frac{\text{TBP}}{a}\right)^{1/b}
\]

where \(a = 0.7760\) and \(b = 1.040\) for the interconversion of the 50% points. \(D-2887(\text{SD})\) = vector of simdist boiling point temperatures at 0, 10, 30, 50, 70, 90 and 95 vol.-% distilled, in degrees Fahrenheit, and \(D-86(\text{TBP})\) = vector of observed ASTM D-86 temperatures at corresponding volume percentage distilled, in degrees Fahrenheit.

The procedure works by calculation of differential temperatures from the mid-volume boiling point value and translating that value to the other corresponding member of the pairing.

The difference between adjacent cut points can be determined from a series of equations for each interval.

</tbody>
</table>
(Equation 67):

\[ D-86_{\text{diff}}(I) = C_0(D-2887_{\text{diff}})C_1 \]  \hspace{1cm} (67)

where \( C_0 \) and \( C_1 \) are coefficients for varying temperature ranges, \( D-86_{\text{diff}}(I) \) and \( D-2887_{\text{diff}}(I) \). Their vectors are shown in Table 12. Temperature values and differences are in Rankine or Fahrenheit degrees.

2.11.2.10 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to American Society for Testing and Materials D-86 Distillation – Method 3\(^{(158,159)}\) The methodology here is based on data published by Hewlett-Packard Analyzer Division. It provides a point-to-point translation of data from one assay to the other (Equation 68):

\[ D-86(\ ) = f[D-2887(\ )] \]  \hspace{1cm} (68)

where \( D-2887(\ ) = \text{vector of simdist boiling point temperatures at} \ 0, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 95 \text{ and } 100 \text{ vol.-% distilled, in degrees Fahrenheit,} \text{ and} \ D-86(\ ) = \text{vector of observed ASTM D-86 temperatures at the corresponding volume percentage distilled, in degrees Fahrenheit.}

To determine estimated ASTM D-2887 values from measured D-86 values, reverse the procedure. In actual practice this would require several iterative calculations, no reverse transform function being readily available. It is, in reality, easier and more reliable simply to take GC data if the information is needed on any sort of regular basis.

The equations for simdist(\ ) to D-86(\ ) are Equations (69–77):

\[ \begin{align*}
D-86_{\text{IP}} &= 46.57 + 0.5829D-2887_{10\%} + 0.3480D-2887_{\text{IP}} \\
D-86_{10\%} &= 33.31 + 0.6156D-2887_{10\%} + 0.3511D-2887_{20\%} \\
D-86_{20\%} &= 22.41 + 0.4890D-2887_{30\%} + 0.2753D-2887_{20\%} + 0.2171D-2887_{10\%} \\
D-86_{30\%} &= 14.43 + 0.4704D-2887_{30\%} + 0.2837D-2887_{20\%} + 0.2278D-2887_{50\%} \end{align*} \]  \hspace{1cm} (69–72)

To determine calculated ASTM D-2887 values from measured D-86 values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.

2.11.2.11 Conversion of Simulated Distillation (American Society for Testing and Materials D-2887) to True Boiling Point Distillation at 760 mmHg\(^{(9)}\) The methodology here is based on API Technical Data Book (1994) Procedure 3A3.3.

Equations (78) and (79) are used to interconvert ASTM D-2887 and ATM TBP distillation data:

\[ \begin{align*}
\text{TBP}_{50\%} &= a(D-2887_{50\%})^b \\
\text{D-2887}_{50\%} &= \left( \frac{\text{TBP}}{a} \right)^{1/b} \end{align*} \]  \hspace{1cm} (78, 79)

where \( a = 0.8718 \) and \( b = 1.026 \) for the interconversion of the 50% points, TBP temperatures at 0, 10, 30, 50, 90 and 95 vol.-% distilled, in degrees Rankine, and D-2887 = observed ASTM D-2887 temperatures at corresponding volume percentage distilled, in degrees Rankine.

The procedure works by calculating differential temperatures from the mid-volume boiling point value and translating that value to the other corresponding member of the pairing.

The difference between adjacent cut points can be determined from a series of equations for each interval (Equation 80):

\[ \begin{align*}
\text{TBP}_{\text{diff}}(I) &= C_0(D-2887_{\text{diff}})C_1 \\
\text{D-86}_{50\%} &= 4.876 + 0.960D-2887_{50\%} \\
\text{D-86}_{70\%} &= 0.911 + 0.5198D-2887_{70\%} + 0.3326D-2887_{70\%} + 0.1016D-2887_{30\%} \\
\text{D-86}_{90\%} &= 0.279 + 0.7594D-2887_{90\%} + 0.2833D-2887_{95\%} - 0.098D-2887_{100\%} \\
\text{D-86}_{95\%} &= -1.973 + 0.6146D-2887_{95\%} + 0.3191D-2887_{95\%} \\
\text{D-86}_{100\%} &= 34.18 + 1.1486D-2887_{95\%} - 0.5921 \\
&\quad \times D-2887_{90\%} + 0.3154D-2887_{100\%} \end{align*} \]  \hspace{1cm} (73–77)

To determine calculated ASTM D-2887 values from measured D-86 values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.
To determine calculated ASTM D-2887 values from measured TBP values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.

### 2.11.2.12 Conversion of Simuldist Distillation (American Society for Testing and Materials D-2887) to American Society for Testing and Materials D-1160 Distillation – Method 3 \cite{158}

The methodology provides a point-to-point translation of data from one assay to the other (Equation 87):

$$D_{1160}(\%) = f[D_{2887}(\%)].$$ \hspace{1cm} (87)

where D-2887( ) = vector of simuldist boiling point temperatures at 0, 5, 10, 20, 30, 40, 50, 60, 70, 80, 90, 95 and 100 vol.-% distilled, in degrees Fahrenheit, and D-1160( ) = vector of observed ASTM D-1160 temperatures at the corresponding volume percentage distilled, in degrees Fahrenheit.

To determine estimated ASTM D-2887 values from measured D-1160 values, reverse the procedure. Unfortunately, this would require several iterative calculations, no reverse transform function being readily available. It is, in reality, easier and more reliable simply to take actual GC data if the information is needed on any sort of regular basis.

The equations for simuldist( ) to D-1160( ) are Equations (88–99):

1. $D_{1160_{10\%}} = 12.64 + 1.865D_{2887_{10\%}} + 0.1127D_{2887_{1P}} - 0.9729D_{2887_{80\%}}\quad (90)$
2. $D_{1160_{20\%}} = 32.45 + 1.199D_{2887_{20\%}} - 0.2398D_{2887_{80\%}}\quad (91)$
3. $D_{1160_{30\%}} = 10.39 + 1.282D_{2887_{30\%}} - 0.3070D_{2887_{10\%}}\quad (92)$
4. $D_{1160_{40\%}} = 7.249 + 1.117D_{2887_{40\%}} - 0.1464D_{2887_{30\%}}\quad (93)$
5. $D_{1160_{50\%}} = -7.867 + 1.151D_{2887_{50\%}} - 0.1702D_{2887_{10\%}}\quad (94)$
6. $D_{1160_{60\%}} = -20.78 + 2.172D_{2887_{60\%}} - 1.187D_{2887_{50\%}}\quad (95)$
7. $D_{1160_{70\%}} = -28.28 + 0.0398D_{2887_{70\%}} + 0.9497D_{2887_{80\%}}\quad (96)$
8. $D_{1160_{80\%}} = -56.82 + 1.302D_{2887_{80\%}} - 0.2840D_{2887_{80\%}}\quad (97)$
9. $D_{1160_{90\%}} = -54.74 + 1.040D_{2887_{90\%}}\quad (98)$
10. $D_{1160_{95\%}} = 56.08 + 1.428D_{2887_{95\%}} - 0.2514 \times D_{2887_{50\%}} + 0.2724D_{2887_{100\%}}\quad (99)$

To determine calculated ASTM D-2887 values from measured D-1160 values, reverse the procedure. The units for the above equations are all degrees Fahrenheit.

### 3 PREDICTION OF STREAM/STOCK PROPERTIES FROM INSPECTION PROPERTY DATA

#### 3.1 Property Predictions in General \cite{83,89,134,135,143}

The prediction of physical properties is an absolute necessity for any sort of intelligent process and control engineering. It is also a vital tool in the analysis and synthesis of all industrially important organic compounds. As these statements are true of individual volumes of pure components, so too do they apply to mixtures of these components.

Most methods for estimating the properties of hydrocarbon cut fractions were initially derived from relationships that can be ascertained by examining pure components. Boiling point/MW/gravity is an obvious set of positive monotonic correlations where model matches data for nearly all compounds. Refractive index (RI) and
MW for a specific type of compound (aromatics, paraffins, etc.) is another time-tested functional pairing.

Figures 17, 18(a–c), and 19(a) illustrate the variation of various hydrocarbon pure compound physical properties as a function of carbon number and type.

Several of these pure component mathematical models have been modified and extended into the realm of hydrocarbon “pseudo”-components, a lumping procedure whereby a narrow cut stream is described in terms of one or just a few discrete compounds whose properties are estimated by some of the equations found in this work. MW correlates with gravity and MEABP. Pseudocritical temperature is a strong function of gravity and
MABP. Any of these properties (MW, gravity, NBP) may be well approximated from a knowledge of any other two of the set.

An historic paper by Watson et al.\(^{(152)}\) is a nomograph to predict the AP from \(K_W\), the Watson \(K\) factor, which Figure 19 summarizes graphically, clearly showing the relationship of AP to MW and molecular type.

In other cases, properties of an entire fraction may be estimated from one or two inspection properties taken for the cut as a whole – without any “hypothetical” component lumping being assumed.

None of the methods can be expected to perform perfectly. There is always an error factor involved in the use of any of them. The error derives from two primary sources. The first is in the measurement (bias, average absolute deviations, etc.) of the data upon which the correlation is based. The second is the error of fit for the mathematical derivations from the data. Other error sources include mistranscription from old sources, linear scaling of exponentiation or other transcendental mathematical functions, round off/truncation errors for multiple loop computer processing, change of parameter dimensional units or computational accuracy limitations on significant digits.

Classical statistical analysis tells us that the variance of the correlation is the weighted sum of the variances of the functions and data used to generate the correlation. If all but one of the variances are small, the one that is large will be the determining factor in the overall validity of the fit. Thus, new correlations of any sort are limited by the quality of available data and the amount of work necessary to reduce inaccuracies at all levels of the analysis. Use of established or “tried and true” models is often the preferred means of such estimation.

In the following pages, several legacy prediction methods are presented in addition to some more recently examined and published correlations. Use any of them with care. If they yield results that are unexpected, trust one’s instincts and review the data and math manipulations for suitability. Two separate correlations that predict a single property give results that may vary significantly from one another, in spite of being derived from the same data. In another laboratory facility down the street, quite the opposite may be true. There is enough variation in data, fit and suitability of these methods that one should always “calibrate” real data to the assumed estimation method and use whichever procedure best fits the localized truth the best. For this reason, several similar correlations are presented, based on the gross error of fit for hydrocarbon streams in general. Just because the API Technical Data Committee, for example, fits MW one way does not mean that your data will be so well...
served. The reader should possibly try an alternative method presented here or develop one independently if data calibrations fail to show reasonable accuracy and applicability.

3.2 Property Predictions Derived Directly from Observed Data or Other Derived Properties

The following properties can be estimated or predicted directly from simple inspection property measurements. The predicted properties, themselves, can usually (Watson K is an exception) be readily obtained by one or more standard analysis techniques. It may not always be feasible or timely to do so, so these empirical alternatives are presented here. They have been correlated against a significant amount of real historical data.

The correlations presented here either predict derived properties directly from simple inspection property measurements or they use such derived data in hybrid correlations.

3.2.1 Aniline Point

For pure components, several resources\(^{59,63,80,92,96,109}\) provide tables on the APs of various pure hydrocarbons. This is illustrated by Figure 19(a). Within any hydrocarbon family, the AP increases with MW. Aromatics tend to have the lowest and paraffins the highest values of AP. It is a straightforward exercise to construct a predictive method for the APs for pure compounds, based on MW and compound type.

Several nomographs exist which can be used to estimate APs for petroleum fractions. The Winn nomograph is a traditional part of the API Technical Data Book\(^{109}\) as Figure 2B6.1. The original Watson nomograph is shown here in Figure 19(b).

The recommended procedure for predicting the CN index of petroleum fractions with lots of information is a recently developed (rereregressed) version of the ASTM D-4737-87 procedure. This correlation most accurately predicts the data but requires the liquid density and distillation temperatures at three different specific points.

Other classical AP prediction procedures based on disparate property data are also presented here.

3.2.1.1 Aniline Point from American Petroleum Institute Gravity and Distillation Data – Method 1

The AP can be estimated from known stream gravity and boiling point by this method (Equation 100):

\[
\text{AP} = 0.317(\text{D-86}_{50\%}) + 0.40(\text{D-86}_{50\%})(\text{API}) - 298
\]

where D-86\(_{50\%}\) is the cut mid-boiling temperature (degrees Rankine) and API is the API gravity of the cut.

3.2.1.2 Aniline Point from American Petroleum Institute Gravity and Distillation Data – Method 2

An alternative equation to (89) is Equation (101):

\[
\text{AP}^\circ = -151.0 + 0.254\text{MEABP} - 2.87\text{MEABP}^{0.6667}\text{SG} + 34.6\text{MEABP}^{0.3334}\text{SG}
\]

where AP and MEABP are in degrees Rankine.

Equation (101) is more accurate than Equation (100) but it is more complex and requires derived knowledge of the MEABP. It can be estimated as a mid-volume (50%) point or VABP, but the resulting accuracy of the equation will be no better than the previous correlation.

3.2.1.3 Aniline Point from Gravity and Watson K\(^{156}\) – Method 1

Another derivation of boiling point and gravity is the Watson K characterization factor. It correlates extremely well with AP (Equation 102):

\[
\text{AP}^\circ = \frac{K_W - 8.3 - 0.0032(\text{API})}{0.0153}
\]

where API is the measured or assumed API gravity.

Equation (102) is known as the Woodle method (current API method 2B6.1) and is the API’s recommended method, given a lack of complete quality data. One algebraic rearrangement of this correlation is Equation (103):

\[
\text{AP}^\circ = \frac{6.36[\text{MEABP}]^{1/3}}{\text{SG}} - 267.5 - \frac{296.0}{\text{SG}}
\]

Another derivative expression of this correlation is Equation (104):

\[
\text{AP}^\circ = -1254 - 0.139\text{MEABP} + 107.8K_W + 868.7\text{SG}
\]

For a narrow range cut, one could conceivably substitute the TBP 50% point or the VABP into the equation. Studies of this idea showed an average error of approximately 8% by doing this. Equation (93) is now API TDB procedure 2B9.1.

The estimated accuracies of AP correlations are given in Table 14.

3.2.1.4 Aniline Point from Gravity and Cetane Index – Method 1

Equation (105) is used:

\[
\text{AP}^\circ = 67220 + 7.39(\text{API}) - 1.714(\text{CI}) + 2255 \times \frac{\ln(\text{CI})}{\text{API}} - 70600 \frac{\ln((\text{API})^2 / \text{CI})}{\text{API}}
\]

where API is the measured or assumed API gravity.
Table 14: Estimated accuracy of AP correlation (AP range 26–250 °F)

<table>

Method 2. Equation (106) was formulated as a simple derivation of Equation (105):

\[ \text{AP}^\circ\text{F} = 60.39 - 0.82\text{(API)} + 2.36\text{(CI)} \]  (106)

This procedure, although very simple, is slightly less accurate than using Equation (105). It is reported here, however, as it makes a differential equation relating AP to gravity or CI very simple to evaluate for control or planning optimization systems.

An analysis of the errors for the procedure is given in Table 15.

Both methods tend to predict values higher than experiments. The errors of this method increase greatly when predicted rather than measured CI values are used.

3.2.1.5 Aniline Point from Gravity and Flash Point
This method relates the AP to the FP of petroleum fractions. This correlation differs from the previous one because it uses the experimental CI to predict the AP of the fraction from Equation (107):

\[ \text{AP}^\circ\text{F} = 84 + 0.994\text{(API)} + 0.18\text{FP} - \frac{10\text{API}^2}{\text{FP}^{1.5}} \]  (107)

where FP is the flash point (°F) and API is the measured or assumed API gravity.

3.2.1.6 Aniline Point from Smoke Point
Equation (108) is used:

\[ \text{AP}^\circ\text{F} = 12 \times 140 \left( \frac{\text{SP} + 3500 + 3021 \ln(\text{SG})}{3522(\text{SG}) - 1} \right) \]  (108)

where SP is in (mm height).

The validation statistics for these methods are given in Table 16. Equation (97) is now API procedure 2B14.1.

3.2.2 Cetane Index\(^{52,53,147}\)

3.2.2.1 Cetane Index from American Petroleum Institute Gravity and Distillation Data – Method 1
CI can be estimated from known stream gravity and boiling point by one of two methods found in ASTM D-976 (1991–1995 versions) and ASTM D-613 (Equation 109) (temperatures in degrees Fahrenheit).

\[ \text{CI} = C_7(D-86_{50}\%)^2 + C_6(D-86_{50}\%) + C_5(\log\text{MBP})^2 \]
\[ + C_4(\text{API})(\log\text{MBP}) + C_3(\text{API})^2 \]
\[ + C_2(\log\text{MBP}) + C_1(\text{API}) + C_0 \]  (109)

where \( \log\text{MBP} \) = the logarithm of D-86 mid-boiling point, i.e. (Equations 110 and 111)

\[ \text{MBP} = \log(D-86_{50}\%) \]  (110)
\[ \text{MBP} = \text{D-976 revised-mean average BP} \]  (111)

and \( C_0–C_7 \) are coefficients defined in Table 17. The 1995 version is the current API method 2B12.1.

3.2.2.2 Cetane Index from American Petroleum Institute Gravity and Distillation Data – Method 2
A simpler correlation that requires only the liquid density and MEABP is suitable for use. This correlation is a revision of the ASTM D-976-91 procedure. This procedure (the current API method 2B12.1) is represented by Equation (112):

\[ \text{CI} = C_7(D-86_{50}\%)^2 + C_6(D-86_{50}\%) + C_5(\log\text{MBP})^2 \]
\[ + C_4(\text{API})(\log\text{MBP}) + C_3(\text{API})^2 \]
\[ + C_2(\log\text{MBP}) + C_1(\text{API}) + C_0 \]  (112)

Table 17: CI correlation parameters (Equation 109)

</tbody>
</table>
\[ CI = 415.26 - 7.673API + 3.505API \log(\text{MEABP}) + 0.186\text{MEABP} - 193.8\log(\text{MEABP}) \tag{112} \]

where MEABP is in (°F).

An analysis of the errors for both methods is given in Table 18.

### 3.2.2.3 Cetane Index from American Petroleum Institute Gravity and Distillation Data – Method 3

A final alternative form of the D-976 method is Equation (113):

\[ CI = 454.7 - 1641S + 774.745S^2 - 0.554(D-86_{50\%}) + 97.803(\log D-86_{50\%})^2 \tag{113} \]

where \( S = \) density (g cm\(^{-3}\)) at 15 °C and D-86\(_{50\%}\) = distillation temperature (°C) of 50% distillate recovery.

These equations are limited to petroleum liquids with a 90% boiling temperature <343 °C (650 °F). ASTM method D-613 tends to overpredict and is only a slight improvement over ASTM D-976-80. The error of Equation (113) is about the same as that for Equation (112).

### 3.2.2.4 Cetane Index from Gravity and Assay Data via Expanded Distillation Curve Usage – Alternate Methods

CI is also calculated using the methods of ASTM D-4737 (Equation 114):

\[ CI = 45.2 + 0.0892\text{TBP}_{10} + (0.131 + 0.901B)\text{TBP}_{50} + (0.0523 - 0.4208)\text{TBP}_{90} + 0.00049 \times (\text{TBP}_{10}^2 - \text{TBP}_{90}^2) + 107S + 605S^2 \tag{114} \]

where CI = calculated cetane index, SG = specific gravity at 15 °C (60 °F) (g cm\(^{-3}\)) and TBP\(_{10,50,90}\) are true boiling points (°F).

An alternate formulation of Equation (103) using D86 values is Equation (115):

\[ CI = C_0 + C_1A + C_2B + C_3C + C_4BD + C_5A^2 + C_7C^2 + C_8D + C_9D^2 \tag{115} \]

where \( A = D-86_{10\%} - 488(°F) \) or \( D-86_{10\%} - 215(K) \), \( B = D-86_{50\%} - 533(°F) \) or \( D-86_{50\%} - 260(K) \), \( C = D-86_{90\%} - 583(°F) \) or \( D-86_{90\%} - 310(K) \), \( D = \exp[-3.5(SG-0.85)] - 1 \). SG is the specific gravity at 15 °C (g cm\(^{-3}\)), D-86\(_{10\%}\) = 10% volume boiling temperature (R or K), D-86\(_{50\%}\) = mid-boiling temperature (R or K) and D-86\(_{90\%}\) = 90% volume boiling temperature (R or K).

CI correlation parameters per Equation (115) are given in Table 19 and correspond to API procedure 2B12.2.

The error analysis of CI by Equations (114) and (115) is as follows: CI range 31–73.0, average absolute error 4.31 °F, average error 4.22% and average bias error 0.23%.

### 3.2.2.5 Cetane Index from Aniline Point Data\(^{(110)}\)

The method represented by Equation (116) is from Alberta Research Corporation’s work. It is fairly good correlation for hydrotreated and hydrocracked heavy naphtha and diesel stocks.

\[ CI = 0.0007685(\text{AP})^2 + 0.471(\text{AP}) + 13.07 \tag{116} \]

where AP is in degrees Fahrenheit.

The reported error analysis of CI by Equation (116) is as follows: AP range 78–166.5 °F, average error 6.43% and average bias error –0.2%.

### 3.2.2.6 Cetane Index from Aniline Point, Density and Viscosity Data\(^{(110)}\)

#### Canadian General Standards Board Correlation

The Canadian General Standards Board (CGSB) estimates CI via Equation (117):

\[ CI = 77.76 + 0.1765(1.0 + \text{AP}) + 0.003867(\text{AP})^2 - 11.62X + 0.584X^2 - 0.6350V_{40c} \tag{117} \]

where AP is in degrees Celsius, \( X \) is given by Equation (118):

\[ X = \frac{T_{10} + T_{50} + T_{90} + 820.0}{200D^2} \tag{118} \]

(g cm\(^{-3}\) \( T_{10} \), \( T_{50} \), \( T_{90} \) = 10, 50 and 90% D-86 distillation temperatures, (°C), \( D = \) density (g cm\(^{-3}\)) at 15 °C (kg L\(^{-1}\)) and \( V_{40c} = \) viscosity at 40 °C (cSt).

The estimated error analysis of CI by Equation (117) is as follows: AP range 83.8–166.5°F, average error 7.46% and average bias error 1.7%.

**Modified Calculated Carbon Aromaticity Index Method.** Equation (119) is used:

\[ CI = -0.3656(\text{CCAI}) + 345.1 \]  

(119)

where CCAI is given by Equation (120):

\[ \text{CCAI} = D - 81 - 141 \log[\log(V + 0.85)] \]  

(120)

where \( D \) is density \((\text{g cm}^{-1})\) at 15°C \((\text{mg L}^{-1})\) and \( V \) is kinematic viscosity at 50°C \((\text{cSt})\). This equation is probably the most promising as a predictor of CI without regard to the source of the diesel stock.

Observed errors of CI by Equation (119) are as follows: AP range 78–166.5°F, average error 5.61% and average bias error 1.5%.

### 3.2.3 Carbon Numbers/Index

A significant portion of any crude stock carbon remains with the heavier residues upon separation, with as little as 0.01 wt-% of the total crude carbon being removed with the gas-oils.

A quick and convenient method was developed for the prediction of the Conradson carbon number (CC) of petroleum fractions. The corresponding data for this correlation were divided into two sections: lower MW gas-oils and higher MW crude oils and residues.

Several equations for carbon number prediction have been reported, as follows:

#### 3.2.3.1 Conradson Carbon Number from American Petroleum Institute Gravity – Method 1

This uses Equation (121):

\[ \text{CC} \text{wt.-%} = -0.2875 + 52.715(\text{API})^{-3.75} \]  

(121)

where \( \text{API} = (141.5/\text{SG}) - 131.5 \). This is the better correlation for gas-oils, where CC are in the range 0.01–5.5 wt-% with API gravities between 11 and 40.

#### 3.2.3.2 Conradson Carbon Number from American Petroleum Institute Gravity – Method 2

For full range crudes and crude/vacuum resid fractions, Equation (122) may be a better choice:

\[ \text{CC(wt.-%)} = -33.63 + 85.08(\text{API})^{-0.25} \]  

(122)

#### 3.2.3.3 Conradson Carbon Number from Watson K and Distillation Data

This prediction method (Equation 123), when used for stocks with API < 25, predicts higher CC values for heavy crudes and residus very well. Stocks with lower CC numbers must be used carefully.

\[
\text{CC}(\text{wt.-%}) = -507.7 + 2.66\text{API} + 0.024\text{MEABP} + 129.4 \\
\times \ln(\text{MEABP})88.29(\text{API})^{-0.15} - 48.63K_w
\]  

(123)

A summary of the error analysis for the above three methods is given in Table 20.

#### 3.2.3.4 Bureau of Mines Correlation Index from American Petroleum Institute Gravity and Distillation Data

This is an alternative method for calculating the CCs of crude oils and residues (Equation 124):

\[
\text{BMCI} = \frac{48640}{D-86_{50\%}} + 473.7\text{SG} - 456.8
\]  

(124)

where \( D-86_{50\%} \) is the mid-boiling temperature (kelvin).

#### 3.2.3.5 Interconversion of Ramsbottom Carbon Number

(American Society for Testing and Materials D-529) and Conradson Carbon Number (American Society for Testing and Materials D-189)

Figure 20 shows the relationship between these two quantities. They are not identical at all. The graph can be represented by Equation (125):

\[
\log \text{RC} = a + b[\log(\text{CC})] + c[\log(\text{CC})]^2
\]  

(125)

where RC is the Ramsbottom carbon (wt-%) and CC is the Conradson carbon (wt-%).

#### 3.2.4 Flash Point

The FP can be estimated from known stream boiling point data by four commonly used and similar methods. On average, the open-cup tests predict a FP 11–17°F higher than that of the closed-cup (Pensky-Martin) estimations. In general, the closed-cup method is used most frequently for light-end fuel oils, whereas the open-cup method is used for the heavier residuum-like fractions.

#### 3.2.4.1 Flash Point from Distillation Data

Preferred methods for open-cup FP value predictions are represented by Equations (126–128):

\[
\text{FP (°F)} = 0.64(D-86_{10\%}) - 100
\]  

(126)

**Table 20** Estimated accuracy of carbon content correlations
where D-8610% is the 10% (measured/estimated) value.

\[
\text{FP} \left( ^\circ F \right) = 0.64 \times (D-86_{10\%} - D-86_{IP}) \quad (127)
\]

This equation is a form also used fairly often.

\[
\text{FP} \left( ^\circ F \right) = 0.68 \times (D-86_{10\%}) - 109.6 \quad (128)
\]

where D-86_{10\%} = 10% (measured/estimated) value and D-86_{IP} = initial point D-86 value. This equation is the preferred API method for open-cup value prediction and is procedure 2B7.1 in the API Technical Data Book.

Equations (127) and (128) are based on an analysis of the API databank, which showed a possible linear relationship between measured FP and the D-86_{10\%} point. The equation's coefficients were developed in a standard regression fashion. Neither has been adopted as a standard as yet, but they are often useful formulations.

Preferred methods for closed-cup value predictions are represented by Equations (129–131):

\[
\text{FP} \left( ^\circ F \right) = 0.75 \times (\text{TBP}_{5\%} - 100) \quad (129)
\]

where TBP_{5\%} (°F) is the 5% (measured or estimated) cut TBP value. This method is based on the author's experience at modeling hydrocarbon distillation units. It is presented as an alternative.

\[
\text{FP} \left( ^\circ R \right)^{-1} = -0.01457 + \frac{2.849}{D86_{10\%}} + 0.001903 \ln(D-86_{10\%}) \quad (130)
\]

where D-86_{10\%} is the 10% (measured or estimated) value in degrees Rankine (note: absolute form). Equation (130) is known as the Riazi FP and is a widely used correlation in industry.

This is known as the Nelson equation and is a widely used procedure.

\[
\text{FP} \left( ^\circ F \right) = 0.69 \times (D-86_{10\%}) - 118.2 \quad (131)
\]

where D-86_{10\%} is the 10% (measured/estimated) value. This method is based on an analysis of the API databank which showed basically a linear relationship between measured FP and the 10% D-86 point. It is the currently preferred API method for closed-cup predictions.
An analysis of the experimental errors of Equations (125) and (130) is shown in Table 21. The use of other equations may yield adequate results, but these should provide the most accurate estimates, short of fitting one’s own proprietary data.

3.2.4.2 Flash Point from Aniline Point and Distillation

Equation (132) is used:

\[
\text{FP}^\circ = 6989 + 6.0(\text{MEABP}) - 7.67(\text{AP}) - 918.4 \ln \left( \frac{\text{MEABP}}{\text{AP}} \right)^{0.8} - 3683 \times \exp \left( \frac{\text{MEABP}}{\text{AP}} \right)^{0.4}
\]

(132)

where AP and MEABP are in degrees Rankine.

3.2.4.3 Flash Point from Aniline Point and Smoke Point

Equation (133) is used:

\[
\text{FP}^\circ = 116814 + 191.0(\text{AP}) + 21.0 \exp \left( \frac{\text{AP}}{\text{SP}} \right)^{0.8} - 9419[(\text{AP} + \text{SP})^{0.5} + 186.0(\text{SP})]
\]

(133)

where AP is in degrees Fahrenheit and SP is in millimeters.

An analysis of the errors for Equations (132) and (133) is given in Table 22.

### Table 39

3.2.5 Diesel Index

DI is not an easy measurement to make on a consistent and repeatable basis, yet it is a very useful parameter for the prediction of several other derived property estimates.

3.2.5.1 Diesel Index as a Function of Gravity and Aniline Point

DI is defined by a calculation based on the aniline gravity constant (AG), which is the product of AP and API gravity (Equations 134 and 135).

\[
\text{AG} = (\text{AP})(\text{API gravity})
\]

(134)

\[
\text{DI} = \frac{\text{AG}}{100}
\]

(135)

3.2.5.2 Diesel Index as a Function of Watson K and Mid-boiling Point

Equation (136) finds DI as a function of Watson K and D-8650%:

\[
\text{DI} = (K_w - 10.45)[-0.03252(\text{D-8650%}) - 400] + 46.83
\]

(136)

where D-8650% = mid-boiling point – D-8650% point (°F).

3.2.6 Smoke Point Prediction

3.2.6.1 Smoke Point from Aniline Point and Gravity Data

Equation (137) is used:

\[
\text{SP} = -255.3 + 2.04(\text{AP}) - 240.8 \ln(\text{SG}) + 7727 \left( \frac{\text{SG}}{\text{AP}} \right)
\]

(137)

where SP is in mm height and AP is in degrees Fahrenheit. This is known as the Jenkins equation and is also the API’s procedure 2B8.1. The average error of the correlation based on API’s databank of experimental measurements is 6.7%, with an average bias of +0.5%. API’s use of predicted APs to extend the correlational databank will increase the error and bias of the procedure to an average of 8.8% and 4.0%, respectively.

3.2.6.2 Smoke Point from Aniline Point and Distillation

Equation (138) is used:

\[
\text{SP} = 0.556 - 0.149(\text{MEABP}) + 0.52(\text{AP}) + 0.75 \left( \frac{\text{MEABP}}{\text{AP}} \right)^2 + 2084 \left[ \exp(\text{MEABP}) \right]^{0.01} \left( \text{AP}^{2.1} \right)
\]

(138)

where SP is in mm height, AP and MEABP are in degrees Fahrenheit.

3.2.6.3 Smoke Point from Flash Point and Distillation

Equation (139) is used:
3.2.7 Cloud Point, Pour Point and Freeze Point correlation. The accuracy of the equation will be no better than the previous mid-volume (50%) point or VABP, but the resulting accuracy of the MEABP. It can be estimated as a function (141), but it is more complex and requires derived parameters where MEABP is in degrees Rankine.

Equation (140) is used:

$$\ln(SP) = -1.19 + \frac{0.677 \times (MEABP)^{0.334}}{SG} - 0.00467 \times (MEABP)$$  \hspace{1cm} (140)

where SG is at 60 °F and MEABP is in degrees Fahrenheit.

3.2.6.5 Smoke Point from Watson K and Distillation Data A simplification of Equation (140) gives Equation (141):

$$\ln(SP)(\text{mm}) = -1.028 + 0.474 \times K_W - 0.00168 \times (MEABP)$$  \hspace{1cm} (141)

where MEABP is in degrees Rankine. Equation (140) (now API TDB procedure 2B10.1) turns out to be slightly more accurate than Equation (141), but it is more complex and requires derived knowledge of the MEABP. It can be estimated as a mid-volume (50%) point or VABP, but the resulting accuracy of the equation will be no better than the previous correlation.

3.2.7 Cloud Point, Pour Point and Freeze Point Predictions$^{(89,113,122,135)}$

These are related measurements and are highly correlated with one another.

3.2.7.1 Cloud Point from Distillation and Gravity Data The API studied a dual-range correlation in this case (Equation 142). The accuracy of either correlation falls off dramatically when it goes out of the temperature ranges shown in Table 24.

$$CP = C_0 + C_1 \times (MEABP)^2 + C_2 \times (MEABP)^SG$$  \hspace{1cm} (142)

where CP is the cloud point (°F) and MEABP is the mean average boiling point (°F). This is API procedure 2B9.1.

3.2.7.2 Pour Point from Gravity, Molecular Weight and Viscosity Data API Technical Databook 1994 procedure 2B11.1 is represented by Equation (143):

$$PP(°F) = 234.955 \times MW^{B} \times (V_{100})^C$$  \hspace{1cm} (143)

$$A = 2.971, \quad B = 0.6124 - 0.4376SG, \quad C = 0.3103 - 0.8328SG, \quad SG \text{ is the specific gravity, } V_{100} = \text{standard 100°F kinematic viscosity (cSt).}$$

See Table 25 for error analysis. When Equation (132) was run against a database of several hundred waxy crude fractions (100 < MW < 800), the average absolute error dropped to ±5.5 °C (10 °F).

3.2.7.3 Freeze Point from Pour Point Data A quick approximation of the PP can be made from either the freeze point (FRP) or the CP of petroleum fractions (Equation 144). The same is true of the other properties, when given one of the three.

$$FRP = 5.252 + 0.9263(PP)$$  \hspace{1cm} (144)

where FRP and PP are in degrees Fahrenheit. This is API procedure 2B10.1.

3.2.7.4 Pour Point from Freeze Point Data Equation (145) is just an algebraic manipulation of Equation (144) that works well:

$$PP = 1.079(PP) - 5.70$$  \hspace{1cm} (145)

where FRP and PP are in degrees Fahrenheit.

Table 24 CI correlation parameters (Equation 142)
3.2.7.5 Cloud Point from Freeze Point Data

The linear Equation (146) gives very good values:

\[ \text{CP} = -5.746 + 1.005\text{(FRP)} \]  

(146)

where FRP and CP are in degrees Fahrenheit.

A second nonlinear equation (Equation 147) will give slightly better results and the extra mathematical complexity is minimal:

\[ \text{CP} = 5696 + 3.866\text{(FRP)} - 2329\text{(FRP)}^{0.18} \]  

(147)

where FRP and CP are in degrees Fahrenheit.

An analysis of the errors for Equations (144–147) is given in Table 26. CPs are in the range 90 to 50 °F and FRPs are in the range −80 to 50 °F.

3.2.7.6 Freeze Point from Cloud Point Data

This is just an algebraic manipulation of Equation (146) above, which works well (Equation 148):

\[ \text{FRP} = 0.995\text{(CP)} - 5.715 \]  

(148)

where FRP and CP are in degrees Fahrenheit.

This linear function (Equation 149) gives very good values:

\[ \text{CP} = 0.9930\text{(PP)} + 4.026 \]  

(149)

where PP and CP are in degrees Fahrenheit.

This correlation is very accurate at predicting either the CP or PP (see Equation 150), given the other quantity. Correlations on experimental data yielded an absolute average error of approximately 2.25 °C (4.05 °F) and an average bias value of approximately ±0.17 °C (0.3 °F).

3.2.7.7 Cloud Point from Pour Point Data

This linear equation (Equation 151) is best for CPs between 0 and 110 °F and MEABPs of 275–840 °F.

\[ \text{CP} = 753 + 136\{1 - \exp(-0.15V_{100})\} - 572\text{(SG)} + 0.0512V_{100} + 0.139\text{MEABP} \]  

(151)

where PP and MEABP are in degrees Rankine, CP is the cloud point in degrees Celsius and MEABP is the mean average boiling point in degrees Rankine.

\[ \text{PP} = 3.85 \times 10^{-8}\text{MEABP}^{0.49} + 1.4 \]  

(152)

where \( z = 0.712\text{MEABP}^{0.315} + 0.133\text{SG} \). The units here are identical with those for Equation (151).

3.2.7.10 Freeze Point from Distillation and Gravity Data

The FRP can be determined from a combination of distillation and gravity data from API procedure 2B11.1 (Equation 153):

\[ \text{FRP} = -2390 + 1826\text{(SG)} + 122.5K_w - 0.135\text{MEABP} \]  

(153)

where FRP and MEABP are in degrees Rankine.

3.2.7.11 Cloud Point from Distillation and Gravity Data

The CP can be determined from a combination of distillation and gravity data from API procedure 2B12.1 (Equation 154):

\[ \log(\text{CP}) = -7.41 + 5.49\log(\text{MEABP}) - 0.712 \times (\text{MEABP})^{0.315} - 0.133\text{(SG)} \]  

(154)

where CP is the cloud point in degrees Rankine and MEABP is the mean average boiling point in degrees Rankine.

**Figure 21** PP vs CP intercorrelation.
3.2.8 Refractive Index Use and Prediction\(^{(9,133)}\)

The RI of a pure compound is easily found in any of several handbooks. It is predictable by an equation such as Equations (155) or (156):

\[
RI = \frac{C_0 + C_1}{MW + C_2} \quad (155)
\]

\[
RI = C_0 + C_1MW + C_2 \quad (156)
\]

where RI is the refractive index (sodium D-line) at 68°F (20°C) and \(C_0\), \(C_1\) and \(C_2\) are defined in various handbooks. The values of the coefficients are consistent within compound types such as \(n\)-alkanes, \(n\)-alkenes, \(n\)-alkylcyclopentanes, etc.

3.2.8.1 Refractive Index of Hydrocarbon Mixtures from Gravity and Boiling Point Data

API Technical Databook (1994) procedure 2B5.1 is represented by Equation (157):

\[
F_H = C_0 \exp[C_1T_b + C_2(SG) + C_3T_b(SG)]T_b^{C_4(SG)} \quad (157)
\]

where \(C_0\)–\(C_3\) are defined in Table 27, \(T_b\) is the MEABP and \(F_H\) is the Huang characterization factor. Then (Equation 158)

\[
RI = \frac{1 + 2F_H}{1 - F_H}^{0.5} \quad (158)
\]

for the RI at 68°F (see Table 28 for analysis of RI correlation).

3.2.9 The Characterization Factor\(^{(103–106)}\)

By far the most universal characterization parameter used in the prediction of hydrocarbon stocks is the Watson \(K\) factor \( (K_W)\). This characterization factor is an important and special physical property of hydrocarbons defined by Equation (159):

\[
K_W = \left[\frac{CABP \, ^{(R)}{1/3}}{SG}\right] \quad (159)
\]

The \(K_W\) factors of pure hydrocarbons are given in Table 29. The values for most petroleum oils lie between 11.0 and 12.0. A straight-run (“Virgin”) gas-oil might have a \(K_W\) of about 11.7, while a cracked gas-oil of similar boiling range might have a \(K_W\) of 11.2. Table 30 lists the Watson \(K\) ranges of some refinery “straight-run” product cuts. Table 31 gives Watson \(K\) ranges of several refinery “cracked” product cuts. The characterization factor of a fraction can be determined to within an accuracy of \(<0.1\) and can be used and interpreted with considerable confidence and reliability.

The most accurate way to determine the characterization factor is from the CABP defined by Equation (8). Also shown are the MW and pseudocritical temperature.

The Watson \(K\) factor may also be estimated from the AP (Figure 19a) and from viscosity–gravity charts.

</table>

Several of the equations presented in section 3 are essentially derivatives of these equations. \( K_W \), however, is still the most widely used characterization factor. One major use of these other factors is the speciation of hydrocarbon cuts by compound type.

The refractivity intercept, \( R \), is estimated by Equations (160) and (161):

\[
R = 1.0482X_p + 1.038X_n + 1.081X_a
\]

(160)

\[
= n - \frac{SG}{2}
\]

(161)

The viscosity–gravity constant, VGC, is estimated by the Equations (162–164):

\[
VGC = 0.774X_p + 0.915X_n + 1.040X_a
\]

(162)

\[
= -1.816 + 3.484(SG) - 0.1156 \ln V_{100}
\]

(163)

\[
= -1.948 + 3.535(SG) - 0.1613 \ln V_{210}
\]

(164)
where $X_p$, $X_n$ and $X_a$ are the mole fractions of paraffins, naphthenes and aromatics, respectively, $n =$ sodium D-line RI of liquid at 20°C, $V_{100}$ is the standard viscosity at 100°F (cSt) and $V_{210}$ is the standard viscosity at 210°F (cSt).

The Huang factor is defined by rearranging Equation (157):

$$ F_H = \frac{n^2 - 1}{n^2 + 2} \quad (165) $$

Coupled with the fact that $X_p + X_n + X_a = 1.00$, Equations (160–165) and (157) can be solved for relative amounts of P, N and A to within an accuracy of approximately 0.05 fraction.

API procedure 2B4.1 presents another estimation procedure. (Equations 166–168):

$$ X_p = A_0 + A_1R + A_2(VGC) \quad (166) $$
$$ X_n = B_0 + B_1R + B_2(VGC) \quad (167) $$
$$ X_a = C_0 + C_1R + C_2(VGC) \quad (168) $$

Coefficients for Equations (166–168) are given in Table 32.

### 3.2.10 Molecular Weight (9,118,120,125)

MW can be measured directly in the laboratory, and there are several means of doing so. The problem is that they are slow, require methodical attention and are, therefore, expensive to use in everyday operations. Gel permeation chromatography (GPC) and GC/MS techniques are two of the more common of these methods.

There are, fortunately, some correlations that do a good job of MW assessment with a minimum of experimental data. Two such correlations are presented here.

#### 3.2.10.1 Average Molecular Weight as a Function of Gravity and Boiling Point

This is expressed by Equation (169):

$$ MW = 20.49 \{ \exp[1.165 \times 10^{-4}T_b - 7.787(SG)] + 1.158 \times 10^{-3} - (T_b)(SG) \} (T_b)^{1.260}(SG)^{4.983} \quad (169) $$

where $T_b$ is the MEABP of the cut (°R) and SG is the specific gravity of the cut.

#### 3.2.11 Critical Properties (64,82,86,118,119,121,132,151,187)

Traditional mixture estimation of a "pseudocritical" property is merely a linear molar-ratio average blend of all the components. Nobody likes this very much but no-one has come up with a general procedure that is significantly better at this time.

#### 3.2.11.1 Critical Temperature as a Function of Gravity and Boiling Point

For a simple hydrocarbon gas we have (Equation 171):

$$ T_c = 94.72 + 170.7(SG) \quad (171) $$

where $T_c$ is the estimated critical temperature (°C) and SG is the gas specific gravity in relation to air at 60°F, 1 atm.

For a hydrocarbon liquid with Engler (90–10) slope >0.5 °C %−1 (Equation 172):

$$ \ln T_c = 3.853 + 0.8799 \ln (SG) + 0.4293 \ln (MABP) \quad (172) $$

For a hydrocarbon liquid with Engler (90–10) slope <0.5 °C %−1 (Equation 173):

$$ \ln T_c = 4.052 + 0.4012(SG) + 0.379 \ln (MABP) \quad (173) $$

where $T_c$ is the estimated critical temperature (°C), SG is the standard SG of the liquid at 60°F and MABP is the molar (not mean) average boiling point temperature (°C).

Another method of predicting hydrocarbon liquid critical temperature is the current API procedure 4D1.1 (Equation 174):

$$ T_c = 186.2 + 1.667Z - 0.7127 \times 10^{-3}Z^2 \quad (174) $$

where $Z = (SG)(VABP + 100)$, $T_c$ is the estimated critical temperature (°F), SG is the standard specific gravity of the liquid at 60°F and VABP is the volumetric average boiling point temperature (°F).

Equation (174) is accurate to within about a 1% average error.
A third valid method of predicting hydrocarbon liquid critical temperature is the current API procedure 4D3.1 (Equation 175):

$$T_c = 10.64 \{ \exp[-5.175^{-3}T_b - 0.5444(SG) + 3.60 \times 10^{-3} \\
\times(T_b)(SG)]} \} (T_b)^{0.8107}(SG)^{0.5369}$$  \hspace{1cm}(175)$$

where \(T_c\) is the estimated critical temperature \(^°\text{R}\), SG is the standard specific gravity of the liquid at 60°F and \(T_b\) is the MEABP temperature \(^°\text{R}\) described in section 2. Equation (175) is accurate to within a 0.8% average error.

It is good in the ranges \(70 < \text{MW} < 295, 80 < T_b < 650\,°\text{R}\) and \(6 < \text{API} < 95\).

### 3.2.11.2 Critical Pressure as a Function of Gravity and Distillation Data

For a hydrocarbon gas (Equation 176):

$$P_c = 48.92 - 4.028(SG)$$  \hspace{1cm}(176)$$

where \(P_c\) is the estimated critical pressure \((10^5 \text{ Pa})\) and SG is the gas specific gravity in relation to air at 60°F, 1 atm.

For a hydrocarbon liquid with Engler (90–10) slope \(>0.5\,°\text{C} \%^{-1}\) (Equation 177):

$$\ln P_c = 8.18 - 1.931 \ln (SG) - 0.8727 \ln (\text{MABP})$$  \hspace{1cm}(177)$$

and for a hydrocarbon liquid with Englers (90–10) slope \(<0.5\,°\text{C} \%^{-1}\) (Equation 178):

$$\ln P_c = 7.742 + 2.802(SG) - 0.7539 \ln (\text{MABP})$$  \hspace{1cm}(178)$$

where \(P_c\) is the estimated critical pressure \((10^5 \text{ Pa})\), SG is the standard specific gravity of the liquid at 60°F and MABP is the molar (not mean) average boiling point temperature \(°\text{C}\).

A third valid method of predicting hydrocarbon liquid critical pressure is the current API procedure 4D4.1 (Equation 179):

$$P_c = 6.162 \times 10^6 \{ \exp[-4.725 \times 10^{-3}T_b - 4.801(SG) \\
+ 3.194 \times 10^{-3}(T_b)(SG)]} \} (T_b)^{-0.4844}(SG)^{4.085}$$  \hspace{1cm}(179)$$

where \(P_c\) is the estimated critical pressure (psia), SG is the standard SG of the liquid at 60°F and \(T_b\) is the MEABP temperature \(^°\text{R}\) described in section 2. Equation (179) is accurate to within a 2.6% average error.

It is good in the ranges: \(70 < \text{MW} < 295, 80 < T_b < 650\,°\text{R}\) and \(6 < \text{API} < 95\).

### 3.2.11.3 Acentric Factor

The acentric factor is an important property that it is necessary to have for the calculation of real and pseudocomponent thermodynamic properties. By definition it is given by Equation (180):

$$w = -\log \left( \frac{P^*}{P_c} \right) - 1.00$$  \hspace{1cm}(180)$$

where \(P^*\) is the vapor pressure of the component at \(T = 0.7T_c\), temperature is in degrees Rankine and pressure in psia for Equations (177) and (178).

API TDB procedure 2A1.1 allows one to estimate the acentric factor if the critical temperature and pressure are known (Equation 181):

$$w = \frac{\ln(P^*/P_c) - 5.927 + 6.096/(T_c)}{(15.25 - 15.69/(T_c))}$$  \hspace{1cm}(181)$$

where \(P\) is the vapor pressure of the component at reduced temperature \(T_r = 0.7T_c, T_c = T/T_c\).

### 3.2.12 Thermal Capacities and Transport Properties

#### 3.2.12.1 Heat of Combustion

An important property of all fuels is the heat of combustion, since this is a measure of the energy available from the fuel. ASTM D-240 is the basis used for the direct determination of heats of combustion of aviation gasolines and of fuel oils. There is an indirect method of calculating or estimating the net heat of combustion of gasolines. The calculation is based on the diesel index (DI) defined according to Equation (182):

$$\text{DI} = \frac{(\text{AP})(\text{API Gravity})}{100}$$  \hspace{1cm}(182)$$

with (Equation 183)

$$\text{Net Btu}{}^{-1} = 17.608 + 20.5\text{DI} - 7.24 \times 10^{-2}(\text{DI})^2$$  \hspace{1cm}(183)$$

where the \text{AP} is in degrees Fahrenheit.

#### 3.2.12.2 Liquid Enthalpy (Reduced Temperature and Pressure \(T_r < 0.8, P_r < 0.98\))

API procedure 12B3.1 provides a way of estimating the enthalpy of an unspecified liquid hydrocarbon mixture (Equation 184):

$$H_L = A_1(T - 259.7) + A_2[T^2 - (259.7)^2]$$

$$+ A_3[T^3 - (259.7)^3]$$  \hspace{1cm}(184)$$

where: \(H_L\) is the liquid enthalpy in Btu lb{}^{-1} \(T\) \(°\text{F}\) is the temperature of interest and (Equations 185–187)

$$A_1 = 10^{-3} - 1171 + (23.72 + 24.91\text{SG})K_W$$

$$+ (1150 - 46.54\text{K}_W)/\text{SG}$$  \hspace{1cm}(185)$$
3.2.12.3 Vapor Enthalpy (T_{r} > 0.8, P_{r} > 0.98) API procedure 12B3.1 provides a way of estimating the enthalpy of an unspeciated hydrocarbon vapor mixture in equilibrium with a saturated liquid (Equation 188):

\[ H_{V} = H_{L}^0 + B_1(T - 0.8T_{pc}) + B_2(T^2 - 0.64T_{pc}^2) + B_3 \times (T^3 - 0.512T_{pc}^3) + RT_{pc}[4.507 + 5.266w] \]  

(188)

where \( H_{V} \) is the enthalpy of an unspeciated hydrocarbon vapor mixture in Btu lb\(^{-1}\), \( H_{L} \) is the saturated (at dew point) vapor enthalpy in Btu lb\(^{-1}\), \( T \) is temperature in degrees Rankine, \( W \) is the reduced temperature below 0.9 (Equation 192):

\[ B_1 = 10^{-3} \left\{ -356.4 + 29.72K_w \right\} + B_4 295.0 - 248.5 \]  

(189)

\[ B_2 = 10^{-6} \left\{ 146.24(77.62 - 2.772K_w) - B_4 301.4 - 253.9 \right\} \]  

(190)

\[ B_3 = -10^{-9}(56.49 - 2.95B_4) \]  

(191)

\[ B_4 = 10^8 \left\{ \frac{12.8}{K_w - 1} \left( 1 - \frac{10.0}{K_w} \right) (SG - 0.885) \right\} \]  

(191A)

For 10.0 < \( K_w < 12.8 \) and 0.70 < \( SG < 0.885 \), else \( B_4 = 0 \).

\( T \) (°F) is the temperature of interest, \( W \) is theacentric factor, \( T_{pc} \) is the pseudocritical temperature (see section 3.12) in degrees Rankine, \( T_{r} = T/T_{pc} \) is the reduced temperature (dimensionless) and \( R \) is the standard gas constant, 1.986 Btu (lb\(^{-1}\) mol\(^{-1}\) R\(^{-1}\)).

3.2.12.4 Isobaric Liquid Heat Capacity of Petroleum Fraction Liquids (\( T_{r} > 0.8, P_{r} > 0.98 \)) The isobaric (constant-pressure) heat capacity of a liquid petroleum fraction is relatively independent of the pressure itself owing to the small compressibility of the liquid. For reduced temperatures below 0.9 (Equation 192):

\[ C_p = X_0 + X_1 T + X_2 T^2 \]  

(192)

where (Equations 193–195)

\[ X_0 = -1.171 + [0.237 + 0.0249(SG)]K_w \]  

\[ + 1.150 - 0.04654K_w \]  

(193)

\[ X_1 = 10^{-4}(1.0 + 0.8246K_w) \left( \frac{1.122 - 0.2763}{SG} \right) \]  

(194)

\[ X_2 = 10^{-8}(1.0 + 0.8246K_w) \left( \frac{2.903 - 0.7096}{SG} \right) \]  

(195)

and \( T \) is temperature in degrees Rankine.

3.2.12.5 Isobaric Vapor Heat Capacity of Petroleum Fraction Vapors (\( T_{r} > 0.8, P_{r} > 0.98 \)) The isobaric (constant-pressure) heat capacity of a vapor-phase petroleum fraction is valid except in the immediate range of criticality (Equation 196):

\[ C_p = X_0 + X_1 T + X_2 T^2 + \) (pressure correction) \]  

(196)

where (Equations 197–200)

\[ X_0 = -0.3654 + 0.2972K_w + X_3 \left( \frac{0.2950 - 0.2485}{SG} \right) \]  

(197)

\[ X_1 = 10^{-4} 2.925 - (1.552 - 0.05543K_w)K_w \]  

(198)

\[ X_2 = 10^{-7}[1.695 + 0.0844X_3] \]  

(199)

\[ X_3 = \left( \frac{12.8}{K_w - 1} \right) \left( \frac{1.0 - 10}{K_w} \right) (SG - 0.885) \]  

(200)

\[ \times (SG - 0.70)(10^4) \]

for 10.0 < \( K_w < 12.8 \) and 0.70 < \( SG < 0.885 \)

\[ = 0 \] for all other values of \( K_w \) and \( SG \)

and \( T \) = temperature in degrees Rankine.

The pressure correction term is a somewhat complex calculation which is beyond the scope of this article. It is zero below about 50 psi and is generally insignificant compared with the error of the correlation below the 150–300 psi range. For higher vapor pressures, any number of good thermodynamic texts will cover the proper use of this factor.

3.2.12.6 Thermal Conductivity – Liquid

Method 1. Liquid Thermal Conductivity as a Function of Molecular Weight. API procedure 12B3.1 provides a way of estimating the enthalpy of an unspeciated hydrocarbon vapor mixture in equilibrium with a saturated liquid (Equation 201):

\[ k = \left( \frac{C_0 + C_1}{MW} + \frac{C_2}{MW^2} \right) + T \left( \frac{C_3 + C_4}{MW} + \frac{C_5}{MW^2} \right) \]  

(201)

where \( k \) is the thermal conductivity of the liquid at temperature \( T \), in units of Btu (lb h°F ft\(^{-1}\))\(^{-1}\) for
where (Equations 210 and 211):

\[
A_1 = 34.93 - 0.08844T_b + 6.735 \times 10^{-5}T_b^2 - 1.014 \times 10^{-8}T_b^3
\]  \hspace{1cm} (210)

\[
A_2 = -2.926 + 0.006984T_b - 5.100 \times 10^{-6}T_b^2 + 7.494 \times 10^{-10}T_b^4
\]  \hspace{1cm} (211)

\(T_b\) is the MEABP of the liquid cut, in degrees Rankine, and \(V_{100}\) is the standard liquid viscosity at 100°F (cSt).

For standard viscosity at 210°F (Equation 212):

\[
\log V_{210} = -1.924 + 2.411 \times 10^{-4}T_b + 0.5113 \log(T_bV_{100})
\]  \hspace{1cm} (212)

where \(T_b\) is the MEABP of the liquid cut, in degrees Rankine, \(V_{100}\) is the standard liquid viscosity at 100°F (cSt) and \(V_{210}\) is the standard liquid viscosity at 210°F (cSt).

3.2.12.9 Density – Liquid  Although usually a quick and easy primary inspection property, densities of petroleum cuts are often estimated or correlated with other variables to evaluate derivatives for determining the interrelational effects of change in a property.

Method 1. Liquid Density as a Function of Molecular Weight and Refractive Index.  API procedure 2B4.1 provides a way of estimating the liquid density of an unspeciated hydrocarbon as a function of MW and RI (Huang index) (Equation 213).

\[
D = 2.831 \text{MW}^{0.3975} F_H^{1.1354}
\]  \hspace{1cm} (213)

where \(F_H\) is given by Equation (214):

\[
F_H = \frac{n^2 - 1}{n^2 + 2}
\]  \hspace{1cm} (214)

\(n\) is the RI at 68°F.

Method 2. Liquid Density as a Function of Standard Viscosity.  API procedure provides a way of estimating the liquid density of an unspeciated hydrocarbon as a function of standard viscosity measurements (Equation 215):

\[
\text{SG} = 0.7717 V_{100}^{0.3975} V_{210}^{1.1354}
\]  \hspace{1cm} (215)

where SG is the liquid specific gravity, \(V_{100}\) is the standard liquid viscosity at 100°F (cSt) and \(V_{210}\) is the standard liquid viscosity at 210°F (cSt).

4 PROPERTY PREDICTION FOR MIXTURES OF KNOWN INDIVIDUAL VALUES

4.1 Introduction

The characterization of a typical petroleum stock is normally based on easily and routinely obtained inspection...
data. How does one handle the case where two stocks, for which a specific inspection property is known for each, are blended? One could estimate average values of gravity and boiling point from some standard mixing rules. For example, gravities blend well linearly with weight percentage or linearly with the inverse of the volume percentage. TBP's blend less well volumetrically but usually give usable results when treated so. With these two quantities, most mixture properties can be estimated. The problem with this technique is that another layer of estimation error has been placed upon the results. Attempts to use simple (i.e. linear) mixing rules to correlate blended values of a hydrocarbon property with the individually estimated or measured blend stock values of the same property have shown marginal results at best.

This difficulty has been overcome by the use of a blend index function and blending numbers, which will be described in this section.

4.2 Blending Index and Numbers

A blend index is a mathematical transformation of a numerical value which can then be blended with other transformed stock values (of the same item) in a reasonably simple algebraic form. The value of the property after transformation is known as the blend number.\(^{(50)}\)

Once the blend number of the mixed stream has been calculated, the actual property value of the blended stream can be determined by performing the inverse of the index transform.

Among the values that are best determined for mixtures in this fashion are viscosity, CP, PP, RVP, FP and AP. Suggested blend index transforms \((f^T)\), mixing and retransform \((f^{-1})\) functions for some of these properties are typically of the form in Equations (216–218):

\[
\text{index}_I = f^T(\text{property.value})_I \tag{216}
\]

\[
\text{property.number}_{\text{mix}} = \text{SUM}[\text{index}_I] \\
\times (\text{vol.pctg.of.stock})_I \tag{217}
\]

\[
\text{property.value}_{\text{mix}} = f^{-1}(\text{property.number}_{\text{mix}}) \tag{218}
\]

where \(I\) is the index of blend stocks from 1 to \(N\) = number of stocks. \(f^T(\ )\) and \(f^{-1}(\ )\) are the chosen property value transform and inverse transform functions, and vary greatly in form from one property to another. The forms presented here are those which have been published and are generally used by the petroleum refining community based on commonly available information. The user may want to use custom/proprietary data to modify the blend index function and its numerical parameters, but the forms shown here are generally the best that the author has found for this purpose.

Table 6 shows a series of gasoline blend components and their corresponding properties. The great majority of blend prediction problems in today's refineries involve gasoline stocks. The important values under EPA [Environmental Protection Agency (US)] Phase II/CARB spec fuels are RVP and distillation values, especially D-86, 90\%.

The other blend methods described in this section, such as CP and PP, are more applicable to jet fuels and heavier stocks.

4.2.1 Viscosity Blend Number

The viscosity blend number (VBN) is best used with volume averaging, i.e. (Equation 219):

\[
\text{VBN}_{\text{average}} = \text{SUM}[(\text{VBN}_I)(\text{volume.pctg.of.stock})_I] \\
\quad \text{where } I = \text{index of blend stocks from 1 to } N = \text{number of stocks}. \tag{219}
\]

4.2.1.1 Index for Viscosity Blending Number at Set Measurement Temperatures\(^{(50)}\) VBN is defined according to Equation (220):

\[
\text{VBN}(\text{at } T_{\text{ref}}) = \frac{\text{viscosity}_\text{mix}}{[\text{VBN}_I(\text{viscosity.cSt})_I]} \times (\log(\text{T}_{\text{ref}}) - \log(\text{T}_{\text{vis}})) \\
\quad + \log[\log(\text{viscosity}_{\text{CS}}) + 0.7] \tag{220}
\]

where API is the API gravity and \(\text{viscosity}_{\text{CS}}\) and \(T_{\text{vis}}\) are any laboratory-measured pair of viscosity (centistokes) and temperature (degrees Rankine). Typical viscosity measurement standards are taken at 100 °F or 40 °C, 150 °F or 66 °C and 212 °F or 100 °C. (Do not forget to convert the temperatures to absolute form before calculating the blend number.)

The viscosity update/transform function to Equation (220) is Equation (221):

\[
\text{viscosity}_{\text{mix}} = \text{VBN}(\text{at } T_{\text{ref}}) \times \frac{K_W}{T_{\text{ref}} - 355} \tag{221}
\]

Separate calculations are required for each standard reference temperature. The values for 100, 140 and 212 °F will, for example, have different blend numbers.

4.2.1.2 General Blend Indices at Various Temperatures

A general VBN that can be used at any standard \(T_{\text{vis}}\) is given by Equation (222):

\[
\text{VBN} = \frac{\log[\log(\text{viscosity}_{\text{mix}} + 0.6)] - 0.834}{0.00265} + 154 \tag{222}
\]
Table 33  VBNs of a typical gas–oil stream

<table>
<thead>
<tr>
<th>Cut point mid (vol.-%)</th>

</tr>
<tr>
<td>76.2</td>
<td>494.6</td>
</tr>
<tr>
<td>81.35</td>
<td>Out of range</td>
</tr>
</tbody>
</table>

where viscosity_{cSt} is the measured centistokes at a standard reference temperature (40, 66 or 100°C).

In the absence of a large amount of data, this method is reasonably good for relating any viscosity measured at any temperature. The VBN method presented here provides only for the prediction of viscosities at the standard temperatures. To determine viscosity at intermediate temperature, one needs to interpolate (extrapolate at your own risk!) from the curve generated at three standard points.

The cut point viscosity data in Table 33 were obtained from a West Texas light vacuum gas-oil (LVGO) cut. Inaccuracies at the extremes of data are common and should be used with caution.

4.2.1.3 Log-linear Blend Function

If no explicit blend data are available, a reasonable guess for the viscosity of a blend of streams, all taken at or referenced to the same temperature, can be estimated by blending the logarithm of the viscosities linearly with equivalent volume fractions of the cuts and retransforming the average by taking the antilogarithm of the value calculated.

4.2.2 Aniline Point Blends (50)

The aniline point (AP) index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (223–225):

\[
\text{AP}_{\text{index}} = \exp(0.003652 \times \text{aniline point}_{I})
\]

\[
\text{AP}_{\text{index mix}} = \text{SUM}[(\text{AP}_{\text{index}}_{I}) \times (\text{volume pctg of stock})_{I}]
\]

where \( I \) is blend stock index for 1 to \( N \) = number of stocks and

\[
\text{aniline point}_{\text{mix}} = \frac{\log(\text{AP}_{\text{index mix}})}{0.003652}
\]

4.2.3 Cloud Point Blends (81)

The cloud point (CP) index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (226–228):

\[
\text{CP}_{\text{index}} = \frac{(\text{cloud point}_{I})^{20}}{600}
\]

\[
\text{CP}_{\text{number mix}} = \text{SUM}[(\text{CP}_{\text{index}}_{I}) \times (\text{volume pctg of stock})_{I}]
\]

where \( I \) is the index of blend stocks from 1 to \( N \) = number of stocks and

\[
\text{cloud point}_{\text{mix}} = (600 \times \text{CP}_{\text{number mix}})^{0.05}
\]

where cloud point is measured in absolute form (degrees Rankine for the equations above).

4.2.4 Pour Point Blends (24,80)

4.2.4.1 Method 1

PP index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (229–231):

\[
\text{PP}_{\text{index}} = \frac{(\text{pour point}_{I})^{12.5}}{600}
\]

\[
\text{PP}_{\text{index mix}} = \text{SUM}[(\text{PP}_{\text{index}}_{I}) \times (\text{volume pctg of stock})_{I}]
\]

where \( I \) is the index of blend stocks from 1 to \( N \) = number of stocks and

\[
\text{pour point}_{\text{mix}} = (600 \times \text{PP}_{\text{number mix}})^{0.08}
\]

where pour point is measured in degrees Rankine.

4.2.4.2 Method 2

An alternative function that the author has used successfully is given by Equations (232) and (233):

\[
\text{PP}_{\text{index}} = \frac{(\text{pour point}_{I})^{9.0909}}{280.6}
\]

\[
\text{pour point}_{\text{mix}} = (280.6 \times \text{PP}_{\text{number mix}})^{0.11}
\]

where pour point is measured in degrees Rankine.

4.2.4.3 Method 3: American Society for Testing and Materials D-97

ASTM D-97 specifies a blend transform function of the following form in Equation (234):

\[
(\text{pour point}_{\text{mix}})^{C_0} = \text{SUM}(V_I^{C_1} T_I^{C_2})
\]

where \( I \) is the index of blend stocks from 1 to \( N \) = number of stocks and \( C_0, C_1 \) and \( C_2 \) are coefficients defined in Table 34.

4.2.5 Reid Vapor Pressure Blends

RVP index blends linearly with the relative volume of each stock. The index, mixing and retransformation functions are given by Equations (235–237):

\[
\text{RVP}_I = (\text{RVP})^{1.25}
\]  

\[
\text{RVP}_{\text{numberr}} = \text{SUM}[\text{RVP}_I] \times (\text{volume}_\text{pctg}_\text{of stock})_I
\]

where \( I \) is the index of blend stocks from 1 to \( N = \) number of stocks and

\[
\text{RVP}_{\text{mix}} = (\text{RVP}_{\text{numberr}})^{0.8}
\]

Of all blended properties, the RVP correlation has the most variation in accepted parameters. Literature values for the index exponent range from 1.07 to 1.32. The user may want to use a customized index function, but a 1.25 index is generally a safe number to start with.

The individual blend values must all correspond to the same blend temperature, 37°C (100°F), if following normal standards.

4.2.6 Distillation Temperature Blends

Several methods of blending TBPs can be derived from the procedures in section 2.

ASTM distillation values cannot be accurately blended in any kind of linear fashion if the range of initial to final boiling point of the cut is greater than about 200°F. This eliminates the heavier cuts altogether and is not a recommended procedure for the lighter cuts either.

A better procedure is to generate the TBP curve for each stock and blend the values based on either volume or weight percentage recovery, depending upon which was used as the independent data acquisition variable. Alternatively, one may take relative volumes of all blend streams at an equivalent boiling point cut and blend these together on a similar pro rata basis. The accuracy of either method is about the same.

The very best TBP blend method is to blend the streams linearly based on the temperature–molar fraction percentage function, but this is a rather complex calculation, and the extra accuracy is often not worth the extra effort. A compromise method comes from the API Technical Data Book, which suggests that TBP values be turned into a molar-based “mean-average” boiling point temperature for a cut fraction. These values are assumed to be linearly blendable at the standard volume fraction recoveries at 10, 30, 50, 70% and 90%.

For wide fraction cuts in general, the API method is recommended. For narrow cuts, simple TBP blending is usually justified.

4.2.7 Flash Point Index Blends

FP index blends linearly with the relative volume of each stock. The two most useful index, mixing, and retransformation functions are as follows.

4.2.7.1 Method 1. Hu–Burns Protocol This is the most commonly used method in industry today (Equations 238–240):

\[
\text{FP}_I = \left( \frac{735.8}{\text{flash point}_I} \right)^{19.61}
\]

\[
\text{FP}_{\text{numberr}} = \text{SUM}[\text{FP}_I] \times (\text{volume}_\text{pctg}_\text{of stock})_I
\]

where \( I \) is the index of blend stocks from 1 to \( N = \) number of stocks and

\[
\text{flash point}_{\text{mix}} = \left( \frac{\text{FP}_{\text{number}}}{735.8} \right)^{0.051}
\]

where flash point is measured in degrees Rankine.

4.2.7.2 Method 2. Whickey–Chittenden Protocol

This is the current API Technical Data Book procedure 2B15.1 (Equations 241–243):

\[
\log(\text{FP}_I) = -6.119 + \frac{4345}{\text{flash point}_I + 383.0}
\]

\[
\text{FP}_{\text{numberr}} = \text{SUM}[\text{FP}_I] \times (\text{volume}_\text{pctg}_\text{of stock})_I
\]

where \( I \) is the index of blend stocks from 1 to \( N = \) number of stocks and

\[
\text{flash point}_{\text{mix}} = \frac{4345}{\log(\text{FP}_{\text{number}} + 6.119) + 383.0}
\]

where flash point is measured in degrees Rankine.

4.3 Other Blend Prediction Methods

4.3.1 Dissolved Gas Effects on Viscosity

One of the most important property estimates that are made incorrectly are liquid viscosity calculations
when dissolved gases are present, even if in known amounts. API Technical Datatabase procedure 11A7.1 presents a reasonable approach to handling this problem (Equations 244 and 245):

\[
V_m = \frac{0.294GLR + 137V_a^{1/3} + 538.4)}{V_a^{1/3}(0.871GLR + 137 + 538.4)}
\]  (244)

\[
V_1 = -1.209 + \frac{1.209 + \log(137V_m)}{T + 139}
\]  (245)

where \(V_m\) is the viscosity (centipoise) of the gas-saturated liquid at 100 °F (37.8 °C), \(V_a\) is the viscosity (centipoise) of the gas-free liquid at 100 °F (37.8 °C), \(V_1\) is the viscosity (centipoise) of the gas-saturated liquid at any Fahrenheit temperature, GLR is the gas–liquid ratio (std. ft³ Bbl⁻¹) or liquid and \(T\) is the temperature at which the viscosity value is desired (degrees Fahrenheit).

4.3.2 Derived Property Blend Rules

Several blend values of streams with calculated or derived properties can be quickly estimated as blends fractionally prorated to volume, weight or molar bases. Among these are the following:

- Watson K (\(K_W\)) – blend is linearly prorated on component weight fraction;
- acentric factor – blend is linearly prorated based on component weight fraction;
- (pseudo)critical temperature – blend is linearly prorated based on component molar fraction;
- (pseudo)critical pressure – blend is linearly prorated based on component molar fraction.

4.3.3 Miscellaneous Property Index Blend Rules of Thumb

It is obvious that prediction of mixture properties is as much art as science. There is no “right” way to generate a blending method. There are a few generalizations, however, that can be listed.

- Critically examine any experimental data that are not monotonically inclined in the direction that one would expect. For example, densities and viscosities of liquids tend to decrease with increasing temperature. It should not have any anomalies over the range of data or one could imply that there is a constraint on its usage (above critical point, bad data, etc.).
- Use a transform method that has a mathematical inverse.
- Base the blend mix on either the dependent (first choice) or independent data acquisition variable. Use derived values for the blending vectors with care. The exception is for intrinsic properties that are based on a relative amount of sample. This would include heating value (Btu per weight unit) or density (weight per volume unit). If the dependent data acquisition value does not correspond to the denominator of the property value units, then one might be well advised to make this transform before blending. The heating value, for example, will be very accurate if estimated on a weight percentage proration, even if the data are based on a volume percentage recovery.
- Try to use a linear blend function. This can be done by proper selection of the transform function. Use of higher ordered blending rules often leads to localized anomalies in the generation of the property–index matrix. These anomalies will probably not correspond to the real world and can drastically disrupt the use of such blend functions in planning, real-time control and optimization operations.

GLOSSARY OF TERMS

Alkane Hydrocarbons conforming to the formula \(C_nH_{2n+2}\) with no saturated bonds or heteroatoms in the molecular structure.

Antiknock Index Synonym for octane rating.

Aromatics Hydrocarbons with at least one fully saturated ring structure, but with no heteroatoms in the molecular structure.

Atmospheric Resid The remainder or bottoms of the crude feed to a distillation column that runs at or near atmospheric pressure. Most of the lighter cuts have been taken off in the tower.

Catalytic Reformer The product of a reaction process that changes naphthenic rings into aromatics. Product changes low octane cut to high octane cut.

Coker/Coking The process/tendency of a hydrocarbon, under thermal stress, to crack and form a mostly carbon solid phase, with simultaneous evolution of some lighter fluid hydrocarbon components.
Conversion Reactor
A chemical process in a refinery that cracks and provides subsequent processing such as hydrogenation and distillation for separation of cuts.

Conversion Refinery
A refinery that has one or more conversion reactors. Typically, most sizeable refineries have at least three of the following units: catalytic cracker, coker/thermal cracker, hydrotreater (usually several), hydrocracker, catalytic reformer.

Cracked
The condition of having long hydrocarbon chains thermally or catalytically broken. In lighter components, the result is often one or more unsaturated bonds between some carbons. In heavier stocks, a mostly carbon (called coke) phase forms with devolution of some lighter hydrocarbons. Thermal cracking is an endothermic process.

Crude Unit
Synonym for the tower/column (or series of same) that first processes crude oil feed to a refinery.

Cut
The name given to a distillation product that is a “cut” of the crude feed. Alternatively, it refers to the measured amounts of analyte that come off the column in specified boiling point or TBP ranges.

D-2887 Distillation
The ASTM standard most often associated with GC analysis of petroleum wide-cut boiling ranges.

Diesel
The cut or fraction of a crude that is used as fuel for compression-ignition engines.

FCC
Acronym for fluid catalytic (“cat”) cracker.

Fluid Catalytic Cracking
The process whereby diesel and gas-oil range hydrocarbons are vaporized cracked with the aid of a heterogeneous catalyst at high temperature. The coke formed in the process is subsequently burned to provide the thermal energy necessary to drive the reactions.

Fraction
Synonym for cut.

Gas-oil (atm, vacuum)
The fraction of a crude feed that is too heavy for diesel fuel and still comes off the column at a higher temperature. It generally makes an excellent feed for FCC and hydrocracker units.

Gasoline
The cut or fraction of a crude that is currently used as fuel for internal combustion engines.

GC
Acronym for gas chromatography.

Hydroprocessing
The process whereby diesel and gas-oil range hydrocarbons are vaporized and cracked in the presence of a hydrogen-rich environment with the aid of a heterogeneous catalyst at high temperature. Very little coke is formed in the process and most unsaturated components are saturated. Depending upon the severity, even aromatics can be hydrogenated.

Hypothetical Component
The name given to the lumping of several dozen to hundreds of individual species of hydrocarbons and related organic compounds into a single TBP boiling range. It can vary from using one to several “hypothetical” compound to represent the entire collection of species.

Kerosine
The standard name for the cut or fraction of a crude that is currently used as fuel for turbine engines or for campfire fuel. It is slightly heavier than gasoline, but much less volatile and dangerous for handling by humans.

Light Ends
The name for an accumulation of very light (lighter than gasoline) collection of hydrocarbons in a distillation column. Alternatively, this term refers to the lighter (as defined by boiling point) few percent of any distillation curve.
<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Multivariate</td>
<td>The use of several types of analysis and characterization of petroleum cuts and fractions to arrive at some sort of speciation of the components, at least by type if not by actual accounting. It involves solution of multiple equations with matrix coefficients taken from several different data sources.</td>
</tr>
<tr>
<td>Naphtha (Light, Heavy)</td>
<td>Gasoline and kerosine boiling range material. Light naphtha refers to the gasoline components, and heavy naphtha refers to the compounds with boiling points nearer the kerosine range. Usually it is synonymous with the top two or three product cuts from the crude unit.</td>
</tr>
<tr>
<td>Naphthenes</td>
<td>Alkanes possessing one or more cyclic but unsaturated rings.</td>
</tr>
<tr>
<td>Octane</td>
<td>The tendency of a naphtha fuel to pre-ignite or “knock” in an internal combustion engine.</td>
</tr>
<tr>
<td>Paraffin</td>
<td>Popular synonym for alkane, also for aliphatic.</td>
</tr>
<tr>
<td>Prefrac Column</td>
<td>A sometimes used device that strips a crude of its lighter naphtha cuts before heating the crude to maximum temperature.</td>
</tr>
<tr>
<td>Pseudo-component</td>
<td>Synonym for hypothetical component</td>
</tr>
<tr>
<td>Real Time</td>
<td>The protocol whereby data about a process are obtained, analyzed and utilized in the control of that process within a short period of time, well under the time constant of the process frequency response function.</td>
</tr>
<tr>
<td>Reduced Crude</td>
<td>The term for either atmospheric resid or for crude that has been run through a prefrac column to remove a significant portion of its lighter naphtha content.</td>
</tr>
<tr>
<td>Resid</td>
<td>The remainder or bottoms of the crude feed to a distillation column that runs at or near atmospheric pressure. Most of the lighter cuts have been taken off in the tower.</td>
</tr>
<tr>
<td>Stabilizer</td>
<td>The common term for a distillation column that is used to strip off very light ends from a hydrocarbon cut in order to make a product specification or safety related reason.</td>
</tr>
<tr>
<td>Straight Run</td>
<td>Synonym for virgin cut as applied to physical distillation fractions.</td>
</tr>
<tr>
<td>TBP Distillation</td>
<td>The generic term for refluxed laboratory distillation that approximates the “TBP” of a petroleum cut or fraction. ASTM D-2892 is ostensibly the standard, but there are so many variations as to make an “official” standard superfluous.</td>
</tr>
<tr>
<td>Thermal Cracking</td>
<td>The process whereby heat is applied to a hydrocarbon, resulting in its “cracking”. Delayed cokers work on what is called a “heat soak” process whereby heavy hydrocarbon cuts will crack noncatalytically if a high enough temperature is maintained in the reactor for a long enough time. One of the products is coke, hence the name “coker”.</td>
</tr>
<tr>
<td>Topping Refinery</td>
<td>A refinery whose sole purpose is to recover fuel quality material by distillation and hot flashing of crude/vapor feeds. No conversion reactors, except for perhaps a coker unit, are found in this type of refinery.</td>
</tr>
<tr>
<td>Tower/Column</td>
<td>The piece of process equipment that is used to separate hydrocarbons on the basis of boiling points by use of a heat source driving all vapors upward and refluxing/condensing the heavier cuts downward by liquid gravity flow. A modern refinery contains dozens of columns. The first unit that a crude feed usually sees is the crude unit, which typically consists of one to three columns operating at different pressure levels.</td>
</tr>
</tbody>
</table>
Transport Properties

The physical properties of a substance that are the primary quantities involved in the characterization of mass, momentum and heat transfer in industrial hydrocarbon processing operations.

Transport Fuels

The naphtha and diesel range cuts that provide the primary bulk of liquid fuels for current domestic transportation methods using some form of a combustion engine, internal combustion, turbine or compression–ignition.

Vacuum Resid

The remainder or bottoms of the crude feed to a distillation column that runs at far below atmospheric pressure. It contains most of the lighter cuts that were not taken off in the atmospheric column. It allows vaporization of components at a lower temperature than at atmospheric pressure, thus reducing the chance of thermal cracking and coking during the processing.

Virgin

Naturally occurring as found in the feed crude oil and not having been processed in a conversion (chemical) reactor. Physical processing such as distillation is acceptable for this nomenclature as long as the chemical structure is not changed.

The field of pharmaceutical analysis includes a wide range of analytes, varying in structure from very simple compounds to complex biomolecules. As such, a host of approaches have been and continue to be used in developing reliable analytical methodology for these analytes. In the broadest sense, there are two types of procedures: those that are designed as simple, reliable means of monitoring formulated products in terms of their identity, strength and quality, and those that are used during the drug discovery and development stages to answer numerous and fundamentally more challenging questions related to safety, therapeutic effectiveness, drug stability and purity, as well as in helping to develop better understanding of the biomechanisms and kinetics.

From the economic standpoint, there is the continuing pressure to reduce production and hence product costs, and from the quality assurance side to develop methods that are more reliable, accurate, and sensitive. Over the last thirty years there has been an increasing reliance on separation-based methods combined with various pre-analysis sample clean-up procedures such as solid phase or supercritical fluid extraction and post-column approaches like derivatization fluorescence detection or electrospray mass spectrometry (MS) to improve their accuracy and sensitivity.

From the regulatory standpoint, an important change that occurred in the United States during the late 1970s was the introduction of Good Laboratory Practices by the Federal Drug Administration. These regulations were the direct result of several perceived problems in the pharmaceutical industry and they resulted in greater accountability in terms of calibration, maintenance and record keeping. With the emergence of an expanding number of multinational companies and increasing global markets, similar trends and demands have followed throughout the world.

From the hardware/equipment standpoint, two of the significant changes that have occurred have been miniaturization and automation. Modern and important techniques that have emerged in the last three decades that have had an important impact on modern pharmaceutical analysis include high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), high-field solution and solids nuclear magnetic resonance (NMR), electrospray MS, and computer automation and robotics. Likewise, in terms of sample handling, solid-phase extraction, supercritical extraction and micro-capillary dialysis sampling have also become important tools.

As the direct result of the above pressures and trends, the increasing competitiveness of the marketplace, and the quest for less expensive, safer, and better drugs with well understood and targeted activities, the pharmaceutical industry has been and continues to be one of the leaders in pioneering new analytical methods. This is easily documented by the thousands of published accounts that appear yearly in the scientific literature, the growth in the job market for those obtaining undergraduate degrees in chemistry and graduate degrees in analytical and allied fields of chemistry, and the growth in vendors marketing analytical hardware and speciality items.

Unfortunately, a “down-side” of the remarkable growth in the field of chemical analysis and the automation of modern analytical instrumentation and procedures has been a greater isolation of the analyst from the fundamental principles governing the measurement being made. There are many excellent methods published daily, but, on the negative side, there are numerous accounts that have appeared which are based on what might be considered less than reliable conditions. Generally, most practicing analytical chemists understand how to make their hardware perform effectively, and they have a reasonable empirical/working knowledge of how to systematically change conditions in order to produce a given result, but they sometimes either fail to consider or choose to ignore relatively simple fundamental concepts that influence the reliability and ruggedness of their methods. Many of the problems associated with assay instability result from poorly designed procedures that may appear to provide the correct result but are not optimized to minimize variability. Thus, it is the intent of the current section to address the field of pharmaceutical analysis from both the technique and the topic standpoints. There are articles included that are based on particular techniques, that are topical in nature, and, in a few cases, that survey/ review the literature from an accounts perspective. A brief overview of each of these follows.
1 ORGANIZATION AND INFORMATION

Alkaloids, Pharmaceutical Analysis of. The alkaloid article provides a historical perspective and topical overview of the analysis of more common and pharmaceutically important, naturally occurring bases. It also includes, in tabular form, a review of representative methodology that has appeared in the literature over the last decade.

Antibiotics, Pharmaceutical Analysis of. The antibiotics article provides a brief introduction to the six major classes of antibiotics, the cephalosporins, penicillins, quinolones, streptomycines, sulfonamides and tetracyclines, as well as several other important miscellaneous compounds such as chloramphenicol, isoniazid and trimethoprim. It also includes extensive tables which contain a survey of the recent literature in terms of the analytical methodology that has been introduced for assaying the six major cases of antibiotics.

Chemical Reagents and Derivatization Procedures in Drug Analysis. Derivatization is often used to improve sensitivity or volatility for analytes measured respectively using liquid or gas chromatography (GC). As such, this article provides a discussion of some of the important derivatization procedures used in combination with either liquid chromatography (LC) or GC.

Chiral Purity in Drug Analysis. With the increasing demand for more effective and targeted drugs, the number of assays for evaluating chiral purity has been expanding. The focus of this article is to provide an overview of approaches currently being used to purify chiral drugs and to measure their enantiomeric purity. Regulatory matters also are discussed.

Combinatorial Chemistry Libraries, Analysis of. The advent of modern combinatorial synthetic methods has made it possible to produce dozens of potential leads in a single experiment. Because of this, there is an expanding demand for rapid and sensitive methods to analyze these compounds. This article discusses important aspects of the topic, including the use of high throughput strategies and approaches for handling small quantities of analytes.

Eluent Additives and the Optimization of High-performance Liquid Chromatography Procedures. LC is by far the single most widely used technique for assaying pharmaceuticals, and in a majority of the reported LC methods, the separations are carried out under reversed-phase conditions. This article presents an overview of important considerations in the selection of eluent additives and addresses why and how they are used to optimize the chromatographic separations.

Gas and Liquid Chromatography, Column Selection for, in Drug Analysis. Two of the most important analytical techniques used in pharmaceutical analysis are GC and LC. At the heart of each of these techniques are reliable and selective columns. This article provides useful information related to column selection.

Mass Spectrometry in Pharmaceutical Analysis. MS has been an important analytical tool in pharmaceutical analysis for many years, and it is the premier gas chromatographic detection technique in terms of sensitivity and specificity. Unfortunately, many early attempts at coupling MS with LC were less successful. However, over the last decade, the development of modern electrospray technology combined with multi-dimensional (i.e. MS/MS and MS/MS/MS) mass spectrometric analysis has made it an important and operationally functional tool. This article considers various aspects of the use of modern instrumentation for the analysis of pharmaceutically important peptides.

Nuclear Magnetic Resonance Spectroscopy in Pharmaceutical Analysis. With the introduction of modern high-field NMR instrumentation and the ability to carry out multi-dimensional and solids experiments, uses of the technique have expanded beyond its important role as the major structural elucidation technique. This article discusses the application of modern NMR techniques in the pharmaceutical field, including its uses in evaluating enantiomeric purity.

Planar Chromatography in Pharmaceutical Analysis. On a historical basis the use of planar (i.e. thin layer) chromatographic methods has always been an important topic in pharmaceutical analysis. Assays based on this technique have served as quick and convenient means of screening compounds for purity and in evaluating their stability as a function of storage conditions. The current article focuses on important topics related to the analysis of pharmaceutical compounds, using modern planar chromatographic approaches.

Proteins and Peptides Purification in Pharmaceuticals Analysis. Interest in the potential use of proteins, protein fragments, and peptide drugs has increased over the last decade. One of the more important analytical aspects of this work has been to develop reliable and convenient means of preparing sufficient quantities of a candidate compound for testing. This article discusses purification approaches useful for these types of compounds.

Quantitative Structure–Activity Relationships and Computational Methods in Drug Discovery. Since the beginning of the modern pharmaceutical industry, the quest for methods of predicting a compound’s activity and toxicity from structural features it has been sought. Although the ability to calculate a many-body problem with the superposition of all of the conformational and motional dynamics is still not possible, much has been done in this area, and the current article discusses important aspects and uses of modern computational approaches in drug discovery.
Robotics and Laboratory Automation in Pharmaceuticals Analysis. This current article addresses important hardware and validation considerations related to the automation of modern pharmaceutical analysis. Likewise, examples of the application of automated and robotic procedures for various dosage forms are given.

Solid-phase Extraction and Clean-up Procedures in Pharmaceutical Analysis. Often the most difficult and time-consuming part of an analysis is rendering the analyte in a form that can be conveniently measured using either a classical or instrumental approach. Sample clean-up is often a topic that is ignored or minimized, but may be the major pitfall in carrying out a successful analysis. The current article addresses important aspects of modern sample preparation, including solid-phase extraction and supercritical fluid extraction.

Steroid Analysis. Steroids represent an important class of compounds that are used to treat a variety of health problems. In many cases, adequate detection is one of the more demanding aspects encountered in developing appropriate analytical methodology. The current article discusses a variety of chromatographic, electrochemical, and spectrometric techniques used to assay steroids, and it presents methodology to evaluate them by therapeutic class.

Vibrational Spectroscopy in Drug Discovery, Development and Production. Modern infrared (IR) spectroscopy has become an increasingly important technique in drug discovery, especially as it relates to product development and production monitoring. This article addresses important instrumental and operational aspects of its use, including different sampling and acquisition techniques.

Vitamins: Fat and Water Soluble, Analysis of. Vitamins fall into two major groups, those that are fat soluble and those that are water soluble. In a number of cases (i.e. the fat-soluble vitamins), very subtle structural differences exist that require relatively demanding separation conditions to obtain the desired assay specificity. The current article considers various analytical procedures that have been developed for each of the two broad vitamin groups.

2 BIOGRAPHICAL SKETCH OF THE AUTHORS

A.P. Argekar: Reader in Chemistry, Institute of Science, University of Mumbai, India. B.S. Karnataka University, M.S. and Ph.D., University of Mumbai, India. Recipient of the Indian Drug Manufacturer’s Best Paper Award in 1996. Research interests include pharmaceutical analysis, environmental science, and separation techniques.

J.J. Bao: Senior Scientist, Procter and Gamble Pharmaceuticals, Inc., Cincinnati, OH, and Adjunct Professor of Chemistry at Shandong University, Jinan, China. Ph.D. (1993) Analytical Chemistry, Purdue University, Indiana. Research interests include HPLC, HPCE (high-performance capillary electrophoresis), micro-total analysis systems, high-throughput electrophoretic separations, and various detection techniques, such as MS and laser induced fluorescence.

A.T. Balaban: Professor of Organic Chemistry, Bucharest Polytechnic University, Romania. Ph.D. Chemical Engineering and Dr. Habil. (1974) in Organic Chemistry, Polytechnic University, Bucharest, Dipl. Radiochemist, Bucharest University and Institute of Atomic Physics, Bucharest. Research interests include synthesis of heterocycles, stable nitrogen free-radicals, nitric oxide donors, catalytic isomerizations of polycyclic aromatic hydrocarbons (PAHs), isotopically labeled compounds, theoretical and computational methods related to drug design, chemical applications of graph theory, topological indices, and molecular modeling.

B. Dawson: Research Scientist, Health Canada, Ottawa, ON, Canada. B.S. (1972) and M.S. (1974) Chemistry from St. Francis Xavier University, Nova Scotia, Ontario,
Ph.D. Chemistry (1981), Carleton University, Ontario, and Postdoctoral Fellow (1982) University of Western Ontario. Research interests include NMR studies of drugs and related materials, structure elucidation of pharmaceutical impurities, degradation products, and metabolites, illicit and "designer" drugs, and natural products, and the applications of NMR spectroscopy for the determination of isomeric content of drugs.

C.S. Gilpin: Research Librarian, Ohio University Eastern. B.S. (1990) and MLS (1992) Library and Information Science, Kent State University St. Clairsville, OH. Research interests include scientific information retrieval, analytical, pharmaceutical and biomedical information, data management and search systems.

R.K. Gilpin: Professor and Dean of the College of Science and Mathematics, Wright State University, Dayton, OH. B.S. (1969) Chemistry, Indiana State University; Ph.D. (1973) Analytical Chemistry, University of Arizona. Editorial Board Member, Journal of Chromatographic Science, and NIH Technology Transfer SSS Member. Research interests include the development of chemically modified surfaces for chromatography, organometallic surface reactions, separation of pharmaceutically and biomedically active compounds, NMR and IR studies of modified surfaces and other ordered systems, and characterization of materials.

C.J. Hann: Senior Scientist, Research Division, Solutia, St. Louis, MO. B.S. (1977) Chemistry, Bradley University, IN, Ph.D. (1988) Analytical Chemistry, Kent State University, OH. Research interests include optimization of separation methodology, development of quality assurance procedures for pharmaceutically and biomedically active leads, and process control analysis.

Board of the *Journal of Chromatography A*. Research interests include the separation of enantiomeric drugs by HPLC and CE.

**N. North**: Team Leader for new automation technology, SmithKline Beecham Pharmaceuticals, UK. Research interests include automation using robotics to develop noninvasive methods for process control.

**S.A. Tomellini**: Associate Professor, Department of Chemistry, University of New Hampshire, Durham, NH. B.S. (1979) University of Rhode Island, Ph.D. (1985) Rutgers University, Visiting Scientist 1991–1992, Laser Biophysics and Spectroscopy Section, Laboratory of Chemical Physics, NIH. Research interests include expert systems in analytical chemistry, FTIR, HPLC, CE, chemical separations, and IR spectroscopy of lipids.

### 3 Conclusion and Future Trends

From the chemical/biological standpoint the more recent introduction of genetic and combinational methods has resulted in and will continue to result in the production of more novel compounds in shorter periods of time. This, in many respects, is like *The Tale of Two Cities*, in that they represent “the best of times” for synthetic chemists, since many potential leads can be produced quickly, and “the worst of times” for their analytical counterparts, in that large numbers of samples will need to be assayed using relatively small quantities of materials. Separation techniques like microcolumn HPLC and CE, coupled with highly specific and sensitive detection methods like electrospray ionization mass spectrometry (ESIMS), will continue to become more and more important. Likewise, improvements in hardware are making ESIMS more reliable and user friendly, and miniaturization and probe design are making other highly specific techniques like NMR more feasible as on-line detection methods.

Although alkaloids are naturally occurring bases, additional generalizations are difficult because they include a wide range of structurally dissimilar compounds. They vary greatly in their chemical and physical properties as well as in their distribution in nature. In some cases certain alkaloids are associated with only a single species of plant, whereas others are more widely distributed between biological groupings of plants, and yet others are found in a wide range of unrelated plants. Likewise, the concentration of a particular compound may be highly localized within a given region of one plant and found predominantly in a different region of another plant. In some cases the levels of an alkaloid may be relatively high and its isolation as a natural product may be economically feasible, whereas in other cases the levels may be extremely low and less commercially desirable. The medicinal use of alkaloids in the form of crude plant extracts has been known for several thousand years and today there are hundreds that have been isolated and characterized. However, very few of them are accepted therapeutically and many of these fit into the broad categories of cinchona, ergot, opium, rauwolfia, tropane, vinca and xanthine alkaloids.

1 INTRODUCTION

1.1 General Information

As a major class of compounds, alkaloids are naturally occurring bases with a wide range of structures, chemical and physical properties, and pharmacological activities. The use of alkaloids as medical agents in the form of crude plant powders and extracts predates the modern pharmaceutical industry by almost four millennia and in some instances prior to modern science, mass poisonings have resulted from their inadvertent usage. This was especially prevalent in Europe during the Middle Ages.

Historically, a primary source of many alkaloids has been flowering plants, although they may be found throughout nature, such as the ergot alkaloids in the grain fungus Claviceps purpurea. The first crude alkaloid extract to be studied chemically was opium, which is derived from the latex of the poppy Papaver somniferum. Although the initial characterization work on opium that led to the isolation of morphine was carried out in the early 1800s, its use as an analgesic and its narcotic properties had been known for centuries before this.

There are often complex relationships between the alkaloids and their occurrence in nature. In some cases, certain alkaloids such as morphine are associated with only a single species of plant, whereas others like L-hyoscyamine are more widely distributed between biological groupings of plants, and yet others (e.g. nicotine) are found in a wide range of unrelated plants. Likewise, the concentration of a given compound may be highly localized within a given area of a particular plant, such as in its leaves, bark, or roots, and this same alkaloid, if present in a different plant, may be found predominantly in another region. In some cases the levels of an alkaloid may be relatively high and its isolation as a natural product may be economically feasible, whereas in other cases the levels may be extremely low and less commercially desirable. A more in-depth discussion of the above items may be found elsewhere.

Although today there are several thousand alkaloids that have been isolated and identified structurally, this article will focus only on a relatively small number that are considered to be pharmaceutically more important in terms of their accepted therapeutic value. Some of these compounds are among the earliest alkaloids identified for their medicinal effects, such as morphine, brucine, caffeine, quinine, cinchonine and colchicine.
1.2 Common Properties

Although most alkaloids are crystalline colorless solids, some of the more complex conjugated compounds such as berberine may be colored or, like quinine, fluorescent. A common chemical feature of the alkaloids are that they are bases, which is the basis for many of the commonly used colorimetric methods and thin-layer chromatography (TLC) spray reagents. These are based on the reaction of either organic (e.g. ninhydrin) or inorganic (e.g. Mayer’s and Dragendorff’s) reagents with the alkaloid to form highly colored products. Beyond this, additional generalizations are more difficult. Structurally, the basic nitrogen or nitrogens (which vary greatly in number and basicity) may be found in a variety of structural environments and hence the equilibrium properties and hydrophobic characteristics vary dramatically between alkaloids.

Illustrated in Figures 1–7 are some of the significant structural differences between a number of the more common pharmaceutically important alkaloids. Nicotine, which is distributed throughout the plant kingdom, is a relatively small molecule with two heterocyclic nitrogens. Similarly caffeine, another widely distributed small molecule, contains four heterocyclic nitrogens but it also contains two additional carbonyl functionalities. Because of their widespread presence and usage, there have been numerous methods developed for assaying both nicotine and caffeine in their natural states and in a host of different formulations and products (Gilpin and Pachla[4–7] and past biannual reviews in this series). Other alkaloids such as berberine, colchicine, and morphine contain only a single nitrogen but are either structurally more complex and/or contain other polar functionalities. For example, the two hydroxyl groups on morphine have a significant influence on its chromatographic properties. Because of these significantly different structural features, the overall ease of analyzing alkaloids and their pharmacological activity vary greatly.

As a result of their basicity, many alkaloids are thermally and photolytically labile, especially in the presence of oxygen. Common breakdown products are the corresponding N-oxides. In the case where the alkaloids contain other reactive groups they may undergo a variety of other reactions and rearrangements. Hydrolysis is often common. As such, during stability testing it is important to evaluate the pharmacetical products for these likely decomposition candidates. In many cases some of these products, as well as other naturally occurring minor alkaloids and related impurities, may be extremely difficult or impossible to distinguish from the target analyte using simple nonseparation-based analytical procedures. Although details concerning the chemical reactivity of the various classes of alkaloids are presented below, more extensive treatments of this topic may be found elsewhere.[1–3]

Commonly, alkaloids, like other organic bases, are stabilized via conversion to their corresponding inorganic or organic salts (i.e. hydrochloride or citrate salts).

1.3 Trends in Analytical Methodology

For over two decades (Gilpin and Pachla[4–7] and past biannual reviews in this series) separation-based procedures have been, and continue to be, the most often used methods for assaying alkaloids and their formulated products. This is consistent with the same trends in other areas of pharmaceutical analysis and often is essential in developing stability-indicating and purity-profiling methods. During this time a variety of techniques have been employed, ranging from simple screening procedures based on the use of an initial thin-layer separation (Table 1[8,9]) in combination with a colorimetric spray reagent (e.g. iodoplatinate, Dragendorff–Munier & Macheboeuf, iodine–potassium iodide reagents[10]) to more elaborate sample pretreatment and work-up procedures in combination with either an isotropic or a gradient elution high-performance liquid chromatography (HPLC) separation. In the latter

instance, assays based on reversed-phase conditions are the most commonly used methods and the most often used eluent additives are simple buffers that are added to control the protonation/deprotonation of the basic nitrogen(s) and hence their retention properties. An in-depth discussion of the influence of eluent pH on solute retention is considered in the article Eluent Additives and the Optimization of High-performance Liquid Chromatography Procedures in this publication.

For many of the alkaloids, one of the more commonly encountered problems in developing reliable reversed-phase assays is peak tailing. This problem often is exacerbated when more than one nitrogen is present in the alkaloid and/or the alkaloid contains other polar substituents. Peak tailing is the result of residual silanol groups that are present on the reversed-phase packing. Because silica is an amorphous material, the number and distribution of these groups change depending on the synthetic route that is employed to produce the silica, which in turn dramatically influences the nature and performance of the reversed-phase packings. To the practicing chromatographer, this problem manifests itself as manufacturer-to-manufacturer and batch-to-batch differences in column performance for a given stationary phase. Additionally, this problem is exacerbated for solutes that have polar functional groups that can interact strongly with residual silanols such as amines and heterocycles, which are common structural features of alkaloids. In order to minimize the residual silanol problems, one of four approaches are generally used: postreaction end-capping; preparation of sterically blocking phases; electronic manipulation of the attached surface groups; and the use of mobile phase additives. The first three of these approaches are controlled by the manufacturer and are important considerations when purchasing a column, especially for strongly interacting solutes like some of the alkaloids. Although the performance of commercially available bonded phases has improved dramatically, there are still many reversed-phase applications where residual silanol activity leads to unacceptable chromatograms in terms of severely tailing peaks, and as columns age the problem of exposed silanol groups increases even for high-performance bonded phases. Many of these unwanted effects can be eliminated or at least minimized through the use of secondary mobile phase additives. Such problems usually can be addressed by the addition of compounds to the eluent that dynamically modify the surface by a competitive sorption mechanism and hence act to suppress undesirable interactions that can arise between basic solutes and residual silanols. The agents used to do this are strongly sorbing compounds (i.e. molecules that contain a polar head group and a nonpolar tail) that do not interfere with detection. The most commonly used compounds to mask silanol activity and hence to improve peak symmetry are alkylamines, however, in a few cases other compounds (e.g. perfluoralkyl surfactants) have been employed. Alkylamines also are used to enhance the performance of normal-phase separations both in terms of HPLC procedures and in terms of routine TLC screening methods (Table 1).

2 GENERAL INFORMATION AND ANALYTICAL METHODS

2.1 Cinchona Alkaloids

The medicinal value of this group of alkaloids has been known since the 17th century, when crude extracts from cinchona bark, a plant species indigenous to the Andes, were first used for the treatment of malaria. Although there have been more than two dozen cinchona alkaloids that have been isolated and identified, four of the pharmaceutically more important compounds are quinine, quinidine, cinchonidine and cinchonine. The structures of these are given in Figure 1. They are made up of two parts: a quinoline nucleus and a quinuclidine moiety. Of these, quinine and quinidine are the primary alkaloids of various species of Cinchona and Remijia and are present at levels of 1–4% and 0.3–3%, respectively.

Upon oxidation, quinine, quinidine, cinchonidine and cinchonine are converted to the corresponding ketones and they undergo acetylation to form O-acetyl derivatives that reconvert to the starting material on hydrolysis. The vinylic group is susceptible to acid attack and rearrangements. In the case of quinine and quinidine, this tendency is greater than it is for the methoxy group. Greater details

Figure 1 Common cinchona alkaloids.
concerning the chemical reactivity and related properties of these compounds may be found elsewhere.\textsuperscript{1,2}\par

Typically, the cinchona alkaloids are white solids that form sparingly water-soluble mono-salts or highly water-soluble bis-salts. One of the more distinctive spectral features is their fluorescence in acidic media, which has been used in their direct spectrofluorimetric determination as well as by HPLC in combination with fluorimetric detection. Each of these alkaloids has two sites of protonation with respective $pK_1$ and $pK_2$ values in the 5.1–5.8 and 9.7–10.0 ranges.\textsuperscript{16} When assayed using reversed-phase HPLC conditions, these are the structural features that must be appropriately controlled in order to obtain optimum separation performance.

A representative listing of some of the many methods published for the more common cinchona alkaloids is presented in Table 2.\textsuperscript{17–40}

### 2.2 Ergot Alkaloids

Historically, the medical value of some of the ergot alkaloids has been known for over 3000 years. They are the oldest known mycotoxins and are found in the \textit{Claviceps purpurea}, a filamentous fungus that grows on rye and other gramineaceous crop plants. During the Middle Ages in Europe, ergot poisoning through their vasoconstriction and/or hallucination actions was a common occurrence. In a single epidemic in AD 944 it has been reported that about 20 000 people in France died from ingesting ergot-infested flour.\textsuperscript{11}

A common structural feature of many of the ergot alkaloids is their tetracyclic ergoline nucleus, as illustrated.

AA, Atomic absorption; FIA, flow injection analysis; LC, liquid chromatography; MS, mass spectrometry.
in Figure 2. Although all contain an indole structure, some of the clavine compounds, for example, chanoclavine-I and -II and rugulovasine A and B, may contain fewer rings and some of the more complex compounds, for example, the peptide alkaloid ergotamine, contain additional ring systems. The ergot alkaloids can be divided into four subgroups: the clavine alkaloids; the lysergic acid derivatives; the lysergic acid amides; and the ergot peptide alkaloids. Some of the more common compounds are chanoclavine-I (a precursor of agroclavine and elymoclavine), ergonovine, ergotamine and d-lysergic acid.

The most commercially important ergot compounds belong to the peptide subgroup. Typically these compounds must be protected from air oxidation, light, and heat. They hydrolyze to form lysergic acid, proline, a second amino acid, an α-keto acid and ammonia. In the case of ergotamine, a compound used for its antimigraine properties, the hydrolysis products are lysergic acid, proline, L-phenylalanine, pyruvic acid and ammonia. The ergot alkaloids form colored products with sulfuric acid and a characteristic blue product with p-dimethylaminobenzaldehyde. In many cases a double bond is present at either the 8,9-position (e.g. agroclavine, chanoclavine-I and -II, and paspalic acid) or the 9,10-position (e.g. ergotamine, peniclavine, setoclavine, and d-lysergic acid) (Figure 2). These differences can be distinguished in their respective ultraviolet (UV) spectra where λ_{max} is at 284 nm for the indole structure (i.e. the Δ^{8,9} compounds) and at 318 nm for the 4-vinyl indole structure (i.e. the Δ^{9,10} compounds). This difference in UV properties between the two types of structures for the Δ^{8,9} and Δ^{9,10} alkaloids can be used in combination with variable or dual-wavelength detection to impart additional specificity to HPLC-based methods.

A representative listing of some of the methods published for the more common ergot alkaloids is presented in Table 3. A

### 2.3 Opium Alkaloids

The opium alkaloids have been studied more than any other group. They are derived from the latex of a single species of the poppy *Papaver somniferum* and consist of several closely related compounds, including codeine, morphine, neopine, oripavine, and thebaine. Of these, morphine is the most abundant. A second related group of morphinane alkaloids include sinomenine and hasubananone, metapename, and protometapename. These latter alkaloids are found in Japanese *Sinomenium* and *Stephania* plants. The structural difference between these two groups of compounds is shown in Figure 3.

![Common opium alkaloids](image-url)
The first compound to be isolated in pure form from crude opium extracts was morphine, by Serturner in 1805, although 2 years prior to this Derosne had reported the separation of a mixture of morphine and noscapine. The presence of these compounds occurs in nature at levels of 4–21% and 4–8%, respectively.\(^{(1)}\) Subsequently, codeine was isolated in 1833. This latter compound also can be produced easily via O-methylation of the phenolic group in morphine. Likewise, codeine can be oxidized at this same position to form the corresponding ketone, codeinone, which also results from the acid hydrolysis of thebaine.\(^{(3)}\)

In general the morphinandienones can undergo two types of acid-catalyzed rearrangements, forming either aporphines or dibenzazonines. The synthesis and various reaction pathways of this group of compounds are well established.\(^{(1–3)}\)

Typically the morphinandienones have UV maxima at 235–240 and 275–280 nm. However, for sinomenine, where the double bond at the 4,5-position is missing, the \(\lambda_{\text{max}}\) is at 232 and 265 nm. The mass spectrometric,

### 2.4 Rauwolfia Alkaloids

Although approximately 150 species of plants belong to the Rauwolfia genus, *R. serpentina*, a plant found in India, is the most important member. However, other species such as *R. vomitoria* and *R. tetraphylla*, which are found respectively in Africa and Central America, have become alternative sources. Likewise, synthetically produced reserpine now competes favorable in price with the natural product. The medicinal use of extracts from this family of plants, like the ergot alkaloids, has been known for about 3000 years but the major active compound reserpine, which occurs at about the 1% level, was not isolated and identified until 1952. Other minor (i.e. at about the 0.1% range) alkaloids that belong to this class are ajmalicine, ajmaline, rescinnamine, reserpiline, and yohimbine (see Figure 4).

Like the ergot alkaloids, a common structural feature of the rauwolfia alkaloids is the indole nucleus, as illustrated in Figure 4. Alkaline hydrolysis of reserpine, the principal alkaloid of this class, produces reserpic acid, 3,4,5-trimethoxybenzoic acid, and methanol. Vigorous oxidation of the resulting reserpic acid leads to loss of the indole structure via production of 4-methoxy-N-oxalylanthranilic acid.

### 2.5 Tropane Alkaloids

Tropane alkaloids occur in a variety of *Erythroxylaceae*, *Solanaceae* and *Convolvulaceae* plants, which include *Atropa belladona*, *Datura stramonium*, *Erythroxylon coca*, and *Hyosyamus niger*. The most common compounds in this group are cocaine, *l*-hyoscyamine and its racemized form atropine, hyoscine, scopolamine, and meteloidine (Figure 5). The early use of the tropane alkaloids can be traced to the 16th century both in Europe and South America, where crude preparation of *Atropa belladonna* and dried coca leaves were used, respectively, as medical aids. However, their isolation of the active alkaloids was not until the 19th century. Geiger first prepared *l*-hyoscyamine in 1883 and Wohler prepared cocaine in 1862.

</table>
A significant structural feature of the tropane alkaloids are that they are esters of an organic acid that is attached at the 3-position in either an α- or β-configuration to the central tropane structure. Very gentle neutral hydrolysis of these compounds produces tropine and the corresponding organic acid. In the case of l-hyoscyamine, the most widespread alkaloid of Solanaceae plants, the hydrolysis products are tropine and s-(−)-tropic acid. In the presence of more vigorous thermal and acidic conditions, tropine can undergo additional reactions to form a variety of products, and oxidation of tropine leads to both equatorial and axial N-oxide isomers. This is illustrated in Figure 5 for atropine.

A representative listing of some of the many methods published for the more common tropane alkaloids is presented in Table 6.

2.6 Vinca Alkaloids

There are approximately 100 alkaloids that are present in six species of the genus Vinca. This group of plants are found throughout western Asia and the Mediterranean region of Europe. The most important species are Vinca major and Vinca minor, and the more common compounds include apovincamine, eburnamenine, hervine, reserpinine, sarpagine, (−)-tabersonine, vincadine, vincamajine, and vincamine. Of these, vincamine is the most important alkaloid and may be found at levels up to 2–3%. However, at least half of the vincamine currently used is partially synthesized from tabersonine, and numerous derivatives of vincamine have been prepared.

A typical feature of the Vinca alkaloids is the eburna nucleus, which results in a characteristic mass spectrometric pattern. The major fragmentation pathway occurs via Diels–Alder reaction in the C-ring. The radicals produced can undergo two reaction schemes resulting in two major fragments with m/z differences of 41. For example, in the case of apovincamine, ions are observed at 308 and 267, and for eburnamenine, ions are observed at 249 and 208. However, besides the eburna nucleus, the remaining structural features vary widely between the different alkaloids, as illustrated by eburnamonine, vinblastine and vincamine in Figure 6.

This makes the prediction of chromatographic properties much more unlikely compared to alkaloids with more definable structural changes in terms of their effect on retention (e.g. the common opium alkaloids shown in Figure 3).

A representative listing of some of the methods published for the more common vinca alkaloids is presented in Table 7.\(^{136–141}\)

2.7 Xanthine Alkaloids

The xanthine alkaloids are found throughout nature and the most common compounds in this group are caffeine, theophylline and theobromine. They share a number of pharmacological properties, including central nervous system, cardiac, respiratory stimulant, and smooth-muscle relaxant.

The central structural feature of the xanthine alkaloids is their purine nucleus (lower row of compounds in Figure 6). These three compounds are easily analyzed by a variety of methods, as summarized in Table 8, including many reversed-phase HPLC assays.\(^{53,142–180}\)

2.8 Miscellaneous Alkaloids

There are a wide variety of other alkaloids that vary widely in terms of their source of origin, structure, and pharmacological activities. Because of space limitations it is not possible to consider each of these in a more in-depth discussion, but some of the more important are given in Figure 7 and methods for these as well as other alkaloids are given in Table 9.\(^{181–223}\)

References

An antibiotic is a chemical substance, produced by microorganisms (or recently, synthetic routes) which has the capacity to inhibit the growth of other microorganisms/bacterial agents. The terminology for antibiotics stems from the Latin term of antibiosis and the noun antibiotic was coined by Professor Waksman in 1942. Considered as a single therapeutic class, antibiotics are one of the most diverse groups of medicinal agents. They can be grouped into several subclasses depending on their source, structure and activity. These are the cephalosporins, penicillins, quinolones, streptomycins and tetracyclines. In addition to these agents, the sulfonamides and other miscellaneous compounds are also included owing to their antibacterial activity.

1 INTRODUCTION

Antibiotics include a broad spectrum of compounds that are diverse in structure as well as in their mode of action within an organism resulting from the many different sites where they may block or impede bacterial growth. Common mechanisms of action include the inhibition of cell wall synthesis (e.g. cephalosporin and penicillin), membrane function (e.g. gramicidins, nystatin, and streptomycin), ribonucleic acid metabolism (e.g. griseofulvin and neomycin), deoxyribonucleic acid metabolism (e.g. actinomycin and daunomycin), purine and pyrimidine synthesis (e.g. sparkomycin and tubercidin), protein synthesis (e.g. chloramphenicol, erythromycin, and tetracycline), respiration (e.g. antimycins and oligomycins), and oxidative phosphorylation (e.g. gramicidins and valomycins). In some instances a given antibiotic may influence multiple sites. For example, streptomycin affects both membrane function and protein synthesis, while griseofulvin affects ribonucleic acid metabolism and deoxyribonucleic acid metabolism. Neomycin affects ribonucleic acid metabolism and protein synthesis. They are therapeutically used as antibacterial, antiinfective, antifungal, antiparasitic, antimicrobial and in some cases anticancer drugs. Certain antibiotics like the tetracyclines may have a broad spectrum of activities and inhibit the growth of a range of microorganisms including Gram-negative and positive bacteria, species of rickettsia and mycoplasma, certain protozoa and large viruses while other antibiotics like erythromycin and troleandomycin are more limited in scope.

Penicillins are the oldest recognized antibiotics originating from the pioneering work of Fleming. They have the 3,3-dimethyl-7-oxo-4-thia-1-azabicyclo[3.2.0]heptane-2-carboxylic acid parent structure, I, shown below. The 6 position substitution is respectively a [(aminophenylacetyl)amino], [(phenylacetyl)amino], [(2-propenylthio)acetyl]amino] or [(phenoxyacetyl)amino] group for the common drugs ampicillin and penicillin G, O, and V. Likewise, a close structurally related group of antibiotics are the cephalosporins, II.

Some of the more important pathogens where these antibiotics play a significant role in treatment of infections are Actinomyces israeli, Bacillus anthracis, Clostridium perfringens, Corynebacterium diphtheriae, Diplococcus pneumoniae, Escherichia coli, Hemophilus influenzae, Proteus mirabilis, Shigella dysenteriae, Staphylococcus
pharmaceuticals and drugs

*aureus, Streptococcus hemolyticus, and* *Streptococcus viridans.*

Although most antibiotics are produced totally or in part via fermentation processes, compounds like chloramphenicol are manufactured synthetically. Examples of semisynthetic products are ampicillin, methicillin, oxacillin and phenethicillin. These are synthesized by chemically modifying the patient’s natural product. In some instances, the initially identified semisynthetic compounds have been later found to be produced biosynthetically. Tetracycline is a good example of this type of compound which was initially synthesized via the catalytic dehalogenation of chlortetracycline but was later produced biosynthetically.

Antibiotics, as a major class of pharmaceuticals, have been assayed by a variety of procedures. In many instances these have involved either chromatographic or spectrophotometric methodology. In the latter, a variety of reagents have been used to form highly colored products. In terms of chromatographic procedures reversed-phase high-performance liquid chromatography (HPLC), and more recently capillary electrophoresis methodology, have become increasingly important. In some instances post-column colorimetric reactions have been used to facilitate detection.

The remainder of this article is divided into six major sections with a representative summary of more recent analytical methodology given in tabular form.

## 2 GENERAL INFORMATION

### 2.1 Cephalosporins

The cephalosporins are the second family of β-lactam antibiotics discovered after the penicillins and there are numerous parallelisms between the two families. However, unlike the penicillins, they are generally considered to be broad-spectrum antibiotics for both Gram-positive and Gram-negative pathogens. All of the cephalosporins are semisynthetic derivatives of the natural cephalosporin C antibiotic. Their general mode of action is via inhibiting bacterial wall synthesis similar to the penicillins. There is a marked variation for each cephalosporin against β-lactamase. The most resistant compound against this enzyme is cephalothin.

There are strong historical, biological and chemical similarities between the cephalosporins and the penicillins. The common feature is the β-lactam ring.

*aureus, Streptococcus hemolyticus, and* *Streptococcus viridans.*

Although most antibiotics are produced totally or in part via fermentation processes, compounds like chloramphenicol are manufactured synthetically. Examples of semisynthetic products are ampicillin, methicillin, oxacillin and phenethicillin. These are synthesized by chemically modifying the patient’s natural product. In some instances, the initially identified semisynthetic compounds have been later found to be produced biosynthetically. Tetracycline is a good example of this type of compound which was initially synthesized via the catalytic dehalogenation of chlortetracycline but was later produced biosynthetically.

Antibiotics, as a major class of pharmaceuticals, have been assayed by a variety of procedures. In many instances these have involved either chromatographic or spectrophotometric methodology. In the latter, a variety of reagents have been used to form highly colored products. In terms of chromatographic procedures reversed-phase high-performance liquid chromatography (HPLC), and more recently capillary electrophoresis methodology, have become increasingly important. In some instances post-column colorimetric reactions have been used to facilitate detection.

The remainder of this article is divided into six major sections with a representative summary of more recent analytical methodology given in tabular form.

<td>Cefadroxil</td>
<td>Chromatographic</td>
<td>An isocratic ion-pairing HPLC method has been developed for assaying three cephalosporins (cefadroxil, cephalexin and cefaclor), and two anti-TB drugs (isoniazid and pyrazinamide). The separations are carried out on a C18 column using tetrabutylammonium hydrogen sulfate (0.025 M) in combination with pH 3.0 methanol–acetonitrile–triethylamine. The analyte has been assayed in capsules by reversed-phase HPLC that employs a C18 column, 90:10 water–acetonitrile adjusted to pH 3.5 with phosphoric acid as the eluent, p-hydroxyphenylacetamide as an internal standard and UV detection at 254 nm. The detection limits for the procedure are 0.8 µg mL⁻¹. A comparative study between an HPLC method and a microbiological procedure has been reported. Recoveries were greater than 97% with coefficients of variation below 0.7%. Similarly, multicenter trials have been carried out to evaluate an alternative chromatographic approach. Eighteen different C18 stationary phases and copolymer columns have been evaluated by European Pharmacopoeia and USP HPLC protocols and a recommendation made that poly(styrene–divinylbenzene) columns be used for measuring the analyte. Tablets and capsules containing the analyte have been assayed by one of three approaches that involve treatment with (1) 3-methyl-2-benzothiazoline hydrazone, HCl and Ce(IV) in sulfuric acid, (2) 4-aminophenazone and potassium hexacyanoferrate or (3) 2,6-dichloroquinone-4-chlorimide. The absorbance of the resulting colorimetric products are monitored at 410, 510 and 620 nm, respectively. In addition, cefadroxil has been measured colorimetrically as its Cu(II) and V(V) complexes as well as using two of the procedures reported above for cefaclor. In addition to the above colorimetric approaches, cefadroxil, and the related antibiotics cefamandol, cefoxitin, cefapirin and ceftriaxone, have been studied using circular dichroic spectroscopy. A robotic procedure has been developed for evaluating the content uniformity of cefixime in oral dosage products. The analyte has been converted to the hydroxamic acid analog with 0.3 mL of methanolic 6.25% hydroxylamine hydrochloride–6.25% NaOH and subsequently to a colored 1:3 (metal-to-ligand) complex using methanolic 0.2% Fe(III) perchlorate–1.6% HClO₄. The absorbance of the resulting product, which obeys Beer’s law from 80 to 320 µg mL⁻¹, is measured at 525 nm. The analyte has been assayed in the presence of its dimer and major degradation products using CE. Results compare with those obtained under reversed-phase HPLC conditions. In addition, see the colorimetric procedure for cefixime above. An isocratic HPLC method has been described for the analyte that uses a polystyrene–divinylbenzene column operated at 50 °C and an eluent of 14.5:10.5:75 acetonitrile:0.02 M Na octanesulfonate:0.2 M phosphoric acid:water. A reversed-phase procedure has been developed for studying the storage stability of plastic syringes containing the analyte. The chromatographic separations are carried out on an Ultrasphere-ODS column and detection is at 254 nm. Likewise, ceftazidime has been measured densitometrically following its thin-layer separation. The analyte has been measured at 268.6 nm using its first-derivative UV spectrum. The procedure can be carried out in the presence of corresponding degradation products. High molecular weight impurities have been determined in ceftiofur using aqueous-based size-exclusion chromatography. Linear responses were observed from 0.005 to 9.25 µg of the impurities with detection limits of 0.03%. (continued overleaf)</td>
</tr>
</tbody>
</table>
which is hydrolyzed by β-lactamase. These similarities are key to developing analytical methods for this class of drugs. In view of the chemical structure, it is not unusual that β-lactamase enzyme is capable of hydrolyzing the β-lactam ring of both the cephalosporins and penicillins. The carboxylic group is important to both families of compounds. Antibacterial activity and stability (penicillins vs cephalosporins) is defined by the stereospecificity and geometry of the fused side ring. Side chains and stereochemistry play an important role in determining their antibacterial activity.

A listing of the more common cephalosporins and related analytical methodology that has been developed for assaying them is summarized in Table 1.

2.2 Penicillins

The name penicillin was coined in 1929 by Professor Fleming. Penicillins comprise a large family of natural and semisynthetic agents fermented by *Penicillium* and other soil-inhabiting fungi. The penicillins are noted for bactericidal rather than simply bacteriostatic properties and are nontoxic. The unifying chemical structure among them is the central seven-membered thiazolidine–\(\beta\)-lactam ring system. The nucleus common to all penicillins is the fused thiazolidine–amino-\(\beta\)-lactam that consists of L-cysteine and D-valine. The free carboxyl group of the thiazolidine is essential for therapeutic effectiveness. In 1940 several researchers embarked on a scientific endeavor to identify and isolate this class of compounds and as the result of this important pioneering work the penicillins were instrumental during World War II for treating battle casualties.

Crystalline penicillin drug substance and formulated products are sufficiently pure and stable when stored at room temperature and in a dry state. However, all compounds/products deteriorate rapidly at elevated temperatures or when exposed to moisture. The fundamental course of degradation is hydrolysis of the \(\beta\)-lactam ring.

</table>

(continued overleaf)
A study has been carried out to examine seven isocratic reversed-phase methods for
separating benzylpenicillin and related substances on C8 or C8, phenyl and
poly(styrene–divinylbenzene) columns. The manufacturer’s method, which uses a C8
column and 62 : 38 0.05 M pH 3.5 phosphate buffer–methanol as the eluent, gave the
best selectivity whereas the selectivity on poly(styrene–divinylbenzene) was
poorest. Alternatively, the analyte and related impurities have been assayed by
micellar electrokinetic chromatography using a fused-silica capillary operated at 25 °C
and 12 kV with pH 6.5–40 mM NaH2PO4–150 mM-SDS running buffer and detection at 225 nm.

| Spectrometric     | The analyte has been determined colorimetrically after treating it with dehydroascorbic acid. The approach is specific for penicillins having amino acid side chains and is more accurate and precise than compendia methods. Alternatively, the analyte has been measured at 380 nm following its reaction with acidic formaldehyde at 90 °C for 1 h. The method can be applied to a variety of dosage forms without interferences from excipients, coloring agents and flavor additives. Likewise, acetylcacetone–formaldehyde also has been used to assay the analyte in combination products without interference of cloxacillin and excipients. Several other colorimetric methods have been reported for assaying the analyte. These are based on either oxidizing it with sodium hypochlorite or reacting it with 1-chlorobenzotriazole, formation of a chloranil charge-transfer complex and treatment with acenaphthenequinone. Additional reversed-phase, gel permeation, micellar electrokinetic capillary, electrochemical, spectrometric, and stopped-flow fluorimetric methods may be found elsewhere.

| Ampicillin        | Chromatographic        | An interlaboratory study evaluated several LC assay procedures and found that the USP method was the most selective and that cefadroxil was a better internal standard than caffeine. However, in a second study involving seven sites, consistency across locations was not good. A LC method has been published that uses luminol chemiluminescence detection to obtain enhanced sensitivity. Additional HPLC conditions for this analyte also are available.

| Electrochemical   | Both direct current polarography and differential pulse polarography have been used to assay the analyte in pharmaceutical dosage forms. Prior to carrying out the electrochemical measurements, the analyte is converted to its nitroso derivative using nitrous acid. Linearity of the calibration curves is 8–200 and 2–160 µg mL⁻¹ respectively. Alternative polarographic and conductometric titration methods also have been used to assay the analyte.

| Spectrometric     | The analyte has been determined colorimetrically after treating it with dehydroascorbic acid. The approach is specific for penicillins having amino acid side chains and is more accurate and precise than compendia methods. Alternatively, the analyte has been measured at 380 nm following its reaction with acidic formaldehyde at 90 °C for 1 h. The method can be applied to a variety of dosage forms without interferences from excipients, coloring agents and flavor additives. The analyte also has been assayed colorimetrically after formation of a chloranil charge-transfer complex, reaction with acetylacetone–formaldehyde to form a colored product that is measured at 400 nm and obeys Beer’s law between 8 and 140 µg mL⁻¹ and treatment with other reagents such as dehydroascorbic acid and nitrobenzene. A second-derivative UV procedure has appeared for measuring the analyte and cloxacillin. The formulated product is dissolved in water and spectral readings are made between 260 and 300 nm. The derivative measurements for the two antibiotics are at 269 and 288 nm, respectively. Alternatively, a hydrolysis method has been developed which is specific for ampicillin in the presence of cloxacillin. The suitability of near-IR spectroscopy as an alternative to several compendial tests has been examined and has been found to be able to replace identification, water content and assay for release of ampicillin trihydrate bulk drug substance procedures.

| Azlocillin        | Chromatographic        | A stability-indicating reversed-phase HPLC method has been developed which is capable of resolving degradants formed when the analyte is stored at elevated temperatures.

| Benzylpenicillin  | Chromatographic        | A study has been carried out to examine seven isocratic reversed-phase methods for separating benzylpenicillin and related substances on C8 or C4, phenyl and poly(styrene–divinylbenzene) columns. The manufacturer’s method, which uses a C8 column and 62 : 38 0.05 M pH 3.5 phosphate buffer–methanol as the eluent, gave the best selectivity whereas the selectivity on poly(styrene–divinylbenzene) was poorest. In another study, isocratic reversed-phase HPLC was examined by seven laboratories with the recommendation that it should be combined with gradient elution conditions for purity control.

The analyte and related impurities have been assayed by micellar electrokinetic chromatography using a fused-silica capillary operated at 25 °C and 12 kV with pH 6.5–40 mM NaH2PO4–150 mM-SDS running buffer and detection at 225 nm.
Penicillamine Chromatographic A chiral method has been reported for the analyte that involves its derivatization with oxalic acid. Linearity of the calibration curves are 8–200 and 2–160 µg mL⁻¹, respectively. The procedure also can be used for ampicillin and benzathine penicillin.

Oxacillin Chromatographic See the HPLC method for cloxacillin above.

Nafcillin Spectrometric The fluorescence intensity of nafcillin at 336 nm has been studied as a function of temperature and it has been concluded that control is essential in making reliable measurements since the intensity fell 1.1% for every 1 °C increase. The analyte has been determined in mixtures that contain methicillin by constant-wavelength synchronous fluorimetry in combination with a partial least-squares multivariate calibration. Besides these methods, the solid state of the analyte in frozen aqueous solutions has been studied by low-temperature X-ray powder diffractometry.

Methicillin Chromatographic See the general reversed-phase HPLC methodology presented above.

Dicloxacillin Chromatographic The analyte has been measured at 530 nm. The reaction of the analyte with potassium iodate in acidic media has been investigated. Thermospray MS has been used to investigate the solvent degradation of the analyte.

Cloxacillin Chromatographic Results have appeared from a collaborative LC study for determining cloxacillin in bulk drug, capsules and injectables that had coefficients of variations of less than 1%. Also see the reversed-phase procedures for amoxicillin above and elsewhere. The reaction of the analyte with Ce(IV) and detection at 365 nm.

Cephalothin Chromatographic See the general reversed-phase HPLC methodology presented above.

Carbenicillin Electrochemical Both direct current polarography and differential pulse polarography have been used to assay the analyte in pharmaceutical dosage forms. Prior to carrying out the electrochemical measurements, the analyte is converted to its nitroso derivative using nitrous acid. Linearity of the calibration curves are 8–200 and 2–160 µg mL⁻¹, respectively. The analyte is converted to its nitroso derivative using electrochemical measurements, the analyte is converted to its nitroso derivative using nitrous acid. Linearity of the calibration curves are 8–200 and 2–160 µg mL⁻¹, respectively.

Clavulanic acid Chromatographic The analyte has been measured by the general reversed-phase and amoxicillin methods presented above. Thermospray MS has been used to investigate the solvent degradation of the analyte which has been found to undergo hydrolysis followed by decarboxylation when exposed to aqueous solutions containing either acetoniure or propanol and esterification when stored in either methanol or ethanol.

Spectrometric A stopped-flow fluorimetric kinetic assay has been developed for the simultaneous determination of clavulanic acid and amoxicillin. The method involves the acidic reaction of the analytes with Ce(IV) and detection at 365 nm. Near-IR reflectance spectroscopy has been used for the quality control of cream formulations. Samples are extracted with light petroleum after initially dissolving them in methanolic sodium hydroxide.

Spectrometric A differential colorimetric method has been developed that is based on the initial hydrolysis of the analyte and its subsequent reaction with ferricyanide. The procedure also can be used for ampicillin and benzathine penicillin. An indirect spectrophotometric assay has been introduced for formulations containing the analyte and cloxacillin that involves the acid hydrolysis of the analyte followed by the extraction of the products into carbon tetrachloride and measurements made at 520 nm.

Spectrometric A differential colorimetric method has been developed that is based on the initial hydrolysis of the analyte and its subsequent reaction with ferricyanide. The procedure also can be used for ampicillin and benzathine penicillin. * HPTLC, high-performance thin-layer chromatography; GC, gas chromatography; TLC, thin-layer chromatography; PVC, poly(vinyl chloride); NMR, nuclear magnetic resonance.
This decomposition is catalyzed by penicillinase and various metals.

A listing of some of the more common penicillins and related analytical methodology that has been developed for assaying them is summarized in Table 2. In many cases HPLC, UV, colorimetric and microbiological approaches are commonly used.

2.3 Quinolones

The quinolones are a newer class of antibiotics and work on them continues to expand. The first compound discovered in the class was nalidixic acid and subsequently other related compounds have been synthesized based upon in vitro results and structure–activity relationships. The quinolones inhibit DNA synthesis in bacterial cells but not in mammalian cells of DNA topoisomerase. Likewise, the quinolones have a diverse ability to extinguish the micro-bioactivity of microbes.

The number of published methods for this class of compounds continues to increase. Although chromatographic and spectroscopic based methods tend to dominate, the compounds are also electrochemically active. A listing of some of the more common quinolones and related

| Abamectin        | Chromatographic  | A postcolumn normal-phase HPLC method has appeared for abamectin. Following the separation the analyte is reacted with naphthalene-2-sulfonic acid in an alkaline nonaqueous mixing solvent and the absorbance monitored at 570 nm.  
Amikacin        | Chromatographic  | The analyte has been assayed in the 2–100 µg mL⁻¹ range with relative standard deviations of 0.3–4.2% using a C₁₈ column following its derivatization with o-phthalaldehyde. The effluent absorbance is monitored at 340 nm.  
Bekanamycin      | Chromatographic  | Bekanamycin and other related aminoglycoside antibiotics, including gentamicin, tobramycin, lincomycin, neomycin, kanamycin, and ribostamycin, have been measured in pharmaceutical preparations by CE in combination with EC. In the study both copper wall-jet electrodes and copper ion-capillary electrodes were evaluated and the latter were found to provide superior stability and reproducibility.  
Bleomycin        | Chromatographic  | A rapid reversed-phase method has been reported for measuring bleomycins in commercial products which uses sodium perchlorate as an ion-pairing reagent. The luminescence of bleomycins in combination with Tb(III) has been studied and Tb(III) prepared by a centralized pharmacy service. The major limitation of the approach is that it cannot be applied to solutions that contain sodium chloride.  
Clarithromycin    | Chromatographic  | An HPLC method has been developed that can resolve 15 nonpolar related compounds and process impurities that elute after N-demethyl-N-formyl-6-O-methylerythromycin A in clarithromycin bulk drug. All of the nonpolar compounds can be detected at the 0.02% (w/w) level.  
Clindamycin      | Spectrometric    | Clindamycin has been determined spectrophotometrically as its ion-pair complex with Rose Bengal in a slightly basic medium. The colored product that forms at pH 7.5 is measured at 555 nm. Likewise, the analyte has been assayed by direct conductometric titration using Rose Bengal in a 2 : 1 ethanol–water mixture.  
Dirithromycin    | Chromatographic  | An HPLC method has been reported for dirithromycin that uses a C₁₈ column, an eluent consisting of 44 : 19 : 37 acetonitrile–methanol–50 mM pH 7.5 potassium phosphate buffer, and UV detection at 205 nm.  

PHARMACEUTICALS AND DRUGS
Erythromycin Chromatographic
The analyte has been separated under isocratic conditions using a C\textsubscript{18} column and an acetonitrile–pH 6.5 phosphate buffer eluent containing tetrabutylammonium sulfate. The impurities most frequently observed in commercial samples were the propionate ester of erythromycin C and the amide, N-propionyl-N-demethylerythromycin A.\textsuperscript{(106)}

A multicenter study involving six laboratories and seven columns has been carried out and a method has been recommended for the analyte that uses a wide-pore poly(styrene–divinylbenzene) stationary phase.\textsuperscript{(197)}

An alternative study has been carried out that examines several C\textsubscript{18} columns for their use in separating erythromycin and a gradient elution method has been developed for separating the analyte from seven possible impurities. The method is stated to be simpler, more rugged, faster, and more sensitive than a competing chromatographic procedure that uses a poly(styrene–divinylbenzene) stationary phase and it yields results similar to those obtained by microbiological procedures.\textsuperscript{(198)}

In addition to the above methodology, a host of other HPLC-based procedures have appeared for erythromycin. Examples of these may be found elsewhere.\textsuperscript{(199–203)}

The analyte also has been assayed by CE using a 50 mM pH 7.5 phosphate run buffer and an applied voltage of 20 kV. Likewise, 35% ethanol incorporated into a modified 150 mM pH 7.5 phosphate run buffer and an applied voltage of 30 kV have been used to facilitate the separation of erythromycin from erythromycin C, anhydroerythromycin, and N-demethylerythromycin A.\textsuperscript{(204)}

Spectrometric
Erythromycin and related macrolide antibiotics such as oleandomycin, spiromycin, and tylosin have been measured in fermentation broths after treatment with Fe(III). The product that forms in acetic acid–sulfuric acid is measured at 592 nm.\textsuperscript{(205)} Additional colorimetric procedures have been reported that use bromothymol blue, methylthymol blue, and thymol blue as reagents.\textsuperscript{(206)}

Erythromycin has been determined spectrophotometrically via formation of an ion pair with erythrosine B and measuring the chloroform extract at 560 nm using an excitation wavelength of 544 nm. The method can be adapted to an unsegmented flow-injection system and used to assay the analyte in formulations.\textsuperscript{(207)}

Gentamycin Chromatographic
Injectable solutions containing gentamicin sulfate have been assayed by CE and direct UV detection using a borate buffer.\textsuperscript{(208)} Likewise, the analyte has been analyzed using the CE/EC method for bekamycin above\textsuperscript{(209)} and by LC thermospray MS.\textsuperscript{(209)} In the latter instance a simplex algorithm was used to optimize the separation.

Gramicidin Chromatographic
Formulations containing the analyte have been evaluated by a reversed-phase procedure that involves an initial dilution step with aqueous 35% THF, a subsequent separation at 65 °C using an 8 mm PLRP-S column and 38:62 THF–water as the eluent and detection at 222 nm.\textsuperscript{(210)}

Kanamycin Chromatographic
A reversed-phase LC method has appeared for resolving kanamycin sulfate from kanamycins B, C, and D and from other impurities. The procedure involves a two-step gradient separation on a poly(styrene–divinylbenzene) column using aqueous eluents of 20 or 60 g L\textsuperscript{−1} sodium sulfate, 1.3 g L\textsuperscript{−1} sodium octanesulfonate and 50 mL/10.2 M pH 3.0 phosphate buffer and pulsed EC on a gold electrode following the postcolumn addition of sodium hydroxide.\textsuperscript{(211)} The analyte also has been assayed by the CE/EC method described above for bekamycin\textsuperscript{(212)} as well as by flow injection methodology reported elsewhere.\textsuperscript{(212)} In the latter case, the procedure is linear from 0.1 pM to 10μM and common excipients do not interfere.

Lincomycin Chromatographic
Samples containing the analyte have been analyzed after diluting them appropriately with 0.1 M NaOH and separating the resulting solutions on an 80-cm capillary using 0.1 M NaOH as the electrophoretic medium, an applied voltage of 26 kV and wall-jet amperometric detection at +0.675 V vs Ag/AgCl. Using this approach, lincomycin and lincomycin B can be separated within 15 min with a resolution of 2.3.\textsuperscript{(213)} Lincomycins also have been measured by the CE/EC procedure for bekamycin discussed above\textsuperscript{(205)} as well as procedures appearing elsewhere.\textsuperscript{(214)}

Moenomycin Chromatographic
An HPTLC procedure has been developed for evaluating the purity of moenomycin A, B and C isolated from the fermentation broth of Streptomyces bambergiensis. Separations are carried out on silica gel high-performance plates activated at 110 °C for 30 min and developed using 13:7 1-propanol–25% aqueous ammonia. Subsequently, the plates are visualized by treatment with 1:2 acetic acid–chlorosulfonic acid, heating them at 100 °C for 5–7 min and scanning in reflectance mode at 550 nm.\textsuperscript{(215)}

The relative amounts of the B and C components of neomycin sulfate have been evaluated using silica gel TLC plates, 15:85 methanol–20% aqueous sodium chloride, and fluorescence detection after derivatization with 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole. Likewise, an alternative HPTLC method has been described for neomycin A, B, and C that uses a development solvent of 35:20:20:5 methanol–25% aqueous ammonia–acetone–chloroform, and detection with fluorescamine. | Sulfonamides (general)  | Chromatographic| The reversed-phase behavior of seven common sulfonamides on a C18 column using acetonitrile–phosphate buffer as the eluent have been investigated. A number of different conditions, including buffer concentration, type and concentration of positively and negatively charged pairing reagents, column temperature and the ionic state of the solutes have been evaluated and the optimal eluent suggested for each compound. Systematic studies have been carried out to characterize the general migration properties of many common sulfonamides under various electrophoretic conditions. Similarly, HPTLC has been used to evaluate several sulfonamides. A general procedure has been developed for assaying several common sulfonamides in pharmaceutical preparations that involves their initial derivatization to form the corresponding N-(1-naphthyl)ethylenediamine dihydrochloride azo dyes and subsequent reversed-phase micellar separation using a pH 7 0.05 M SDS eluent containing 2.4% pentanol. The colorimetric reagent p-benzoquinone has been used to measure a variety of sulfonamides in bulk and in dosage forms. Likewise, photochemically induced fluorescence has been found to be a useful approach as FTIR spectroscopy.
| Salazosulfapyridine     | Electrochemical| The voltammetric behavior of the analyte has been studied by square-wave techniques and two methods have been developed for measuring it in aqueous samples and formulations.
| Sulfadimidine           | Electrochemical| The analyte can be measured after reacting it with either salicylaldehyde or cinnamaldehyde. The optimal performance is reached in 30 min at 50°C. The analyte, which is reduced to a hydrazine derivative, can be determined by scanning differential pulse voltammetry and adsorptive stripping voltammetry in tablet formulations with relative standard deviations of 5% or better and detection limits in the range 0.2–0.5 ng mL⁻¹.
| Sulfadimethoxal         | Electrochemical| The voltammetric behavior of the analyte has been studied by square-wave techniques and two methods have been developed for measuring it in aqueous samples and formulations.
| Sulfadiazine            | Chromatographic| The reversed-phase behavior of seven common sulfonamides on a C18 column using acetonitrile–phosphate buffer as the eluent have been investigated. A number of different conditions, including buffer concentration, type and concentration of positively and negatively charged pairing reagents, column temperature and the ionic state of the solutes have been evaluated and the optimal eluent suggested for each compound. Systematic studies have been carried out to characterize the general migration properties of many common sulfonamides under various electrophoretic conditions. Similarly, HPTLC has been used to evaluate several sulfonamides. A general procedure has been developed for assaying several common sulfonamides in pharmaceutical preparations that involves their initial derivatization to form the corresponding N-(1-naphthyl)ethylenediamine dihydrochloride azo dyes and subsequent reversed-phase micellar separation using a pH 7 0.05 M SDS eluent containing 2.4% pentanol. The colorimetric reagent p-benzoquinone has been used to measure a variety of sulfonamides in bulk and in dosage forms. Likewise, photochemically induced fluorescence has been found to be a useful approach as FTIR spectroscopy.
| Sulfadiazine            | Spectrometric  | Flow injection analysis methods based on fluorimetric or photochemically induced fluorescence have been developed for the analyte and also for sulfanilimide, sulfaguanidine and sulfacetamide.
| Sulfadiazine            | Chromatographic| Reversed-phase conditions in combination with EC have been used to assay the analyte and also sulfamerazine and phthalysulfathiazole. The calibration curves are rectilinear for all three drugs over the range 10–90 µM. Likewise, the analyte has been assayed using an alternative HPLC method.
| Sulfadiazine            | Spectrometric  | The analyte has been determined colorimetrically by reacting it with dimethylamino-cinnamaldehyde and measuring the absorbance of the red chromogen that forms at 545 nm. The method is linear over the range 0.4–4.8 µg mL⁻¹. A continuous-flow diazotization approach has been used for determining the analyte in dosage forms and for measuring its dissolution rates. An advantage is that it eliminates the frequent preparation of in situ generated nitrate solutions. Samples containing the analyte are assayed by diluting them with methanol, irradiating the solution with a mercury lamp for 2.5 min, and reading the resulting photochemically induced fluorescence at 353 nm. The method is linear over the concentration range 0.1–4.1 µg mL⁻¹. A similar procedure also can be used to measure sulfamethazine in the presence of sulfamerazine or sulfadiazine. The analyte has been measured in the presence of nonsulfonamide antibiotics using a spectrophotometric partial least-squares multivariate method. The same approach can be applied to sulfamerazine, sulfamethazine, sulfaquinone and sulfathiazole. In addition, the analyte has been determined by direct absorbance monitoring.
| Sulfaguanidine          | Chromatographic| See the HPLC method for sulfadiazine above.
| Sulfamethazine          | Chromatographic| See the HPLC method for sulfadiazine above.
| Sulfamethazine          | Electrochemical| An electrochemical study of the oxidation of sulfamethazine has been carried out at a glassy carbon electrode and based on this an HPLC assay for the analyte, sulfadiazine and phthalysulfathiazole has been developed.
| Sulfamethazine          | Spectrometric  | See the spectrometric method for sulfadiazine above.

</table>
The analyte has been assayed in various formulations by either first-derivative or classical least-squares analysis of the UV methanolic spectra. In the first approach, the absorbance is measured at the zero-crossing wavelengths, 240 nm, and in the second the spectrum is recorded from 200 to 350 nm. Other first-derivative, ratio-derivative and linear absorbance methods also have been reported.

The analyte can be measured in formulations containing sulfamethoxazole via oxidizing it with alkaline persulfate. The stable reaction product is formed after heating for 30 min and it is measured at 355 nm. Beer’s law is obeyed in the concentration range 10–60 µg mL⁻¹.

A systematic study of capillary electrophoretic operating conditions has been carried out and optimized methods for the analysis of various tetracyclines have been reported. Different buffer systems are suggested for the separation of tetracycline, oxytetracycline and demeclocycline from their respective major impurities, including the 2-acetyl-2-decarboxamido derivatives. The nonionic surfactant Triton X-100 and methyl-β-cyclodextrin were found to be useful in obtaining improved selectivity in the case of oxytetracycline and demeclocycline. Additional capillary electrophoretic methodology may be found elsewhere.

The micellar electrokinetic migration behavior of six tetracyclines has been investigated in the pH range 5.0–9.0 using ammonium acetate buffers containing SDS. In addition, several other surfactants also were studied. Complete separation of the analytes were achieved in 8 min on a fused-silica capillary using a 15 mM ammonium acetate buffer containing 20 mM SDS at 15 kV. The use of this procedure to obtain information about octanol−water partition coefficients is also discussed.

A flow injection assay has been developed that uses aminophenazone and Fe(CN)₆ as reagents and it has been used to assay doxycycline, oxytetracycline, rolitetracycline and tetracycline with relative standard deviations <1% for samples in the 10–100 µg mL⁻¹ range.

Other topics of a general nature that have been reported include the analysis of various tetracyclines using simplex optimized flow injection analysis, the use of micellar solutions to enhance the luminescence, the europium-sensitized luminescence of tetracyclines and the loss of tetracyclines via their adsorption on laboratory glassware.

A study has been carried out involving five laboratories and six different columns to demonstrate that the proposed HPLC method could be used to determine the analyte and also major related substances such as demeclocycline and 4-epichlortetracycline.

In two additional cross-laboratory studies, both poly(styrene–divinylbenzene) stationary phases and C₁₈ phases were found to be useful for assaying the analyte with variations among the different laboratories between 1 and 2%. Similarly, the usefulness of polymeric stationary phases for separating the analyte and four related substances has been demonstrated in another study.

Other analytical methodologies that have been reported for chlortetracycline are a TLC purity method that has been found to be comparable to LC approaches, an HPLC procedure for resolving the keto–enol tautomers of the analyte and 4-epi-chlortetracycline in combination with UV and NMR spectroscopy to elucidate their structures.

<td>Tetracycline</td>
<td>Chromatographic</td>
<td>The ruggedness of the USP HPLC method for tetracycline has been evaluated. A statistical analysis of column aging and its effect on the separation performance suggests that a C4 column is to be preferred over a C18 column. Capillary electrophoretic assays have been developed for measuring the analyte in the presence of its degradation impurities that are based on conventional aqueous and nonaqueous approaches. Also see the electrophoretic general methodology above. Several comparative studies have been carried out for methods related to tetracycline including one where four laboratories evaluated seven different columns for suitability, another where a TLC method for the analyte was compared with an HPLC method and a final study involving capillary electrophoretic methodology. Other related TLC and HPLC methods appear elsewhere.</td>
</tr>
<tr>
<td>Demeclocycline</td>
<td>Chromatographic</td>
<td>The analyte has been measured by solid-surface room temperature phosphorescence and by chemiluminescence. In the latter instance, a flow injection approach was employed based on the reaction of the chlortetracycline with KMnO₄ in acidic medium in the presence of a micellar agent. It is linear from 1 to 1000µg mL⁻¹ and has a detection limit of 0.60µg mL⁻¹ for the analyte and 0.40µg mL⁻¹ for tetracycline.</td>
</tr>
<tr>
<td>Doxycycline</td>
<td>Chromatographic</td>
<td>A CE method has been developed for doxycycline that is capable of measuring it in the presence of possible impurities. Likewise, the TLC fluorimetric methodology discussed above for chlortetracycline can be used to evaluate the purity of the analyte.</td>
</tr>
<tr>
<td>Metacycline</td>
<td>Chromatographic</td>
<td>Assays for metacycline have been introduced that use TLC in combination with UV/fluorescence densitometric detection to evaluate its purity.</td>
</tr>
<tr>
<td>Minocycline</td>
<td>Chromatographic</td>
<td>Both capillary zone electrophoresis and HPLC have been used to measure minocycline. In the latter case, acidic eluents in combination with poly(styrene–divinylbenzene) columns are used to resolve minocycline and seven other tetracycline derivatives. The voltammetric behavior of the analyte at a water–nitrobenzene interface has been investigated by normal, semi-differential and semi-integral cyclic voltammetry. Resulting from the work was the development of a semi-differential cyclic voltammetric procedure for measuring the analyte in the range 5–200µg mL⁻¹ with results comparable to those obtained by the USP method.</td>
</tr>
<tr>
<td>Oxytetracycline</td>
<td>Chromatographic</td>
<td>Oxytetracycline has been separated from related impurities and degradation products as its magnesium complex under nonaqueous capillary electrophoretic conditions. The method has been used to assay ointments with high selectivity and good precision. In addition, other CE approaches have been reported for the analyte. Results from a comparison study of past HPLC methods for the analyte have indicated that the use of polymeric stationary phases gives the most promising results. Likewise, TLC methodology has been reported for oxytetracycline and doxycycline that is useful for evaluating their purity. The separations are carried out on silica gel thin-layer plates using 59:35:6 dichloromethane–methanol–water with 10% sodium acetate solution adjusted to pH 9.0 as the development solvent.</td>
</tr>
<tr>
<td>Electrochemical</td>
<td>The analyte has been assayed by first extracting it into cyclohexane and then determining it by direct UV measurements in combination with orthogonal polynomial coefficient corrections to minimize interference from excipients. Other spectrometric procedures described for oxytetracycline include one based on its reaction with sodium molybdate, a flow injection approach that uses a carrier stream of iron(III), and its reaction with hydrogen peroxide catalyzed by copper ion to form a chemiluminescent product.</td>
<td></td>
</tr>
<tr>
<td>Spectrometric</td>
<td>See the methods for chlortetracycline above. In the latter method the limit of detection for the analyte is 0.40µg mL⁻¹. In addition to these continuous flow procedures, other spectrometric methods, as well as a postcolumn time-resolved luminescence method for HPLC may be found elsewhere.</td>

2.4 Streptomycin and Related Analogs

The compounds that fall within this category were originally synthesized as organic bases by appropriate strains of actinomycete (Streptomyces griseus). The first drug isolated from actinomycetes was streptomycin in 1943. Other compounds have loosely been included in this category because they also were biosynthesized via similar microbial routes.

Streptomycin itself is strongly basic with an empirical formula of C21H39N7O12. It and related compounds are stable when dry and they retain full potency at room temperature. However, the presence of moisture will affect their stability. Solutions are normally stable at room temperature in the pH range 3–7 and optimal solution stability is typically between pH 6 and 7. Exposure to light may darken solutions and impact purity.

Analytical methodology that has been developed for assaying streptomycin and its related analogs is summarized in Table 4.

2.5 Sulfonamides and Miscellaneous Antibacterial Agents

Summarized in Table 5 are representative analytical procedures that are useful for assaying a number of the more common sulfonamides and also miscellaneous compounds that possess antibacterial activity. In addition to the wide variety of chromatographic and spectrometric methodology that has appeared, a number of electrochemical assays have been published for this grouping of compounds and various studies have been carried out to characterize their electrochemical behavior.

2.6 Tetracyclines

The tetracyclines comprise a family of both biosynthetic and semisynthetic derivatives that are characterized by an unusual antimicrobial background. They are therapeutically used against both Gram-positive and Gram-negative bacteria and various viruses. However, these compounds (Table 6) are not active against the common cold or fungi. The first tetracycline (7-chlorotetracycline) was discovered in 1948 and it was the second compound to be developed after chloramphenicol as a broad-based antibiotic. Four other tetracyclines were developed from natural sources (duomycin, oxytetracycline, demeclocyclin and tetracycline). Subsequently, rolitetracycline, methacycline, doxycycline and minocycline were produced as semisynthetic derivatives.

All of the tetracyclines have a common skeleton (i.e. an octahydro analog of naphthacene) but differ in their substituents, which has a significant influence on their individual solubilities. The tetracyclines are amphoteric and can be manufactured as both acidic and basic salts. Differences are observed in their stability at elevated temperatures in both acidic and alkaline media, which can have a significant impact on the bioavailability of an individual compound when administered orally. In the dry state both the free compound and its corresponding salts are stable at room temperature when protected from light and moisture. In solution, the compounds undergo both acid and basic hydrolysis (ring cleavage) but the degree of cleavage is dependent upon the particular drug. Bulk drug substance and drug product should be placed in opaque light-protecting bottles and, if optimal stability is desired, a desiccant added to the container.

Summarized in Table 6 are representative procedures that have been developed to assay the tetracyclines. In general, this methodology parallels trends noted above for the other antibiotics.

This article describes both pre- and postcolumn derivatization chemistry used in conjunction with either chromatography or capillary electrophoresis (CE) to facilitate the determination of drugs. Generally, only prederivatization is used in gas chromatography (GC), principally to enhance the volatility, temperature stability, and/or detectability. The GC section considers derivatization of drugs by reagent class: alkylation, acylation, and silylation. The GC sample-handling section describes an approach that combines the extraction and derivatization steps together. Both pre- and postcolumn derivatization are common approaches for high-performance liquid chromatography (HPLC) and many of these methods have been adapted for CE. Derivatization for HPLC is often directed toward aliphatic amines, carboxylic acids, or alcohols that are difficult to detect at low levels by absorbance, luminescence, or electrochemical means. In addition, small hydrophilic molecules upon prederivatization are often converted into larger more hydrophobic compounds, making reversed-phase HPLC easier or even feasible. The HPLC section considers derivatization of drugs based on the following types: alkaloids, amines, antibiotics, barbiturates, carbonyl compounds and carboxylic acids, catecholamines, hydroxy compounds, steroids, and sulfur compounds. For the GC and HPLC sections, tables are included, giving the structures of the more important derivatizing agents, the analytes, and the corresponding reaction products. A brief rationale for derivatization chemistry with CE concludes this article. For CE, derivatization is often done to improve detectability as the path length for absorbance detection is very short and fluorescence can be effective using laser-based systems.

1 INTRODUCTION

Derivatization in conjunction with chromatography or CE can be done either in an off-line mode, often prior to the separation step (prederivatization), or in an online mode (postcolumn derivatization). Generally, only prederivatization is used in GC, principally to enhance the volatility, temperature stability, and/or detectability. Both pre- and postcolumn derivatization are common approaches for HPLC and many of these methods have been adapted for CE. Derivatization for HPLC is often directed toward aliphatic amines, carboxylic acids, or alcohols that are difficult to detect at low levels by absorbance, luminescence, or electrochemical means. In addition, small hydrophilic molecules upon prederivatization are often converted into larger more hydrophobic compounds, making reversed-phase HPLC easier or feasible. For CE, derivatization is often done to improve detectability as the path length for absorbance...
detection is very short and fluorescence can be effective using laser-based systems.

The desirable conditions to be met for precolumn derivatization are (i) the reaction stoichiometry and product structure should be known, (ii) the reaction should be reasonably fast and should proceed quantitatively (or at least reproducibly), and (iii) the derivative should be stable, readily separable, and distinguishable from the starting material. One advantage of the prederivatization approach is that simple equipment is commercially available to allow for the reaction chemistry to be done in the batch mode. Subsequent sample analysis using an autoinjector and a standard unmodified chromatograph is straightforward. Alternatively, the use of a robot to carry out the entire prederivatization chemistry and an HPLC instrument equipped with an autosampler means that the sample throughput will usually be limited by the chromatographic step.

Because postcolumn derivatization involves mixing the column effluent with a reagent or passing it through a reactor to form the derivative before it is detected, the automation step is built in. Sample handling before analysis is minimal, reducing the chance of error from sample loss. The conditions desirable to be met for postcolumn derivatization are (i) although the reaction must be rapid, within about 2 min, and be reproducible, the reaction products do not have to be very stable, (ii) the reagent itself must have no, or a very low, detection response, and (iii) the reactor volume must be small to minimize dilution and band broadening.

The remainder of the article is divided into three major sections: GC, HPLC, and CE. The GC section considers derivatization of drugs by reagent class: alkylation, acylation, and silylation. In addition, a short discussion on sample handling is included. The HPLC section considers the derivatization of drugs based on the following types: alkaloids, amines, antibiotics, barbiturates, carbonyl compounds and carboxylic acids, catecholamines, hydroxy compounds, steroids, and sulfur compounds. A brief rationale for derivatization chemistry with CE concludes this article.

2 GAS CHROMATOGRAPHY

Prior to analysis by GC, compounds containing functional groups with active hydrogens such as COOH, OH, NH, and SH need to be protected. Compounds with these functional groups tend to form intermolecular hydrogen bonds, reducing volatility. They are also thermally unstable and can interact with either fused silica or the stationary phase, causing peak broadening. Several good review sources describing derivatization reagents, reactions, and applications for GC are available. At least one commercial company provides a good overview of the commercial reagents and the apparatus available. Two other references are fairly comprehensive in describing many of the published methods for GC derivatization either by reaction class or by the type of organic compound. A recent overview describing gas chromatography/mass spectrometry (GC/MS) methods for drugs of abuse contains prederivatization protocols. Alkylation, acylation, and silylation reaction chemistries are the most common approaches to derivatization for GC and are the primary focus in this article. A specific example and an overview for each of these reaction classes are described below.

2.1 Alkylation

Alkylation represents the replacement of an active hydrogen, found in an organic acid or amine, by an aliphatic or aliphatic–aromatic (e.g. benzyl) group. Alkylation reactions can also be used to prepare ethers from alcohols such as phenol, thioureas from sulfur compounds, and N-alkylamines, amides, and sulfonamides from amines. One principal chromatographic use is the conversion of carboxylic acids into esters that are stable and volatile with good chromatographic characteristics. Esterification of carboxylic acids has traditionally been done through reaction with an alcohol in the presence of an acid catalyst. Generally, a 1–2-mg sample of the acid is heated with 100 µL of the alcohol (methanol or ethanol) containing 3-M HCl for 30 min at 70 °C. The alcohol is evaporated, leaving the ester as a residue. A faster reaction in only about 2 min using a boiling water-bath is possible with a BF3–methanol solution (Table 1, reagent 1). Often the esters are extracted into n-heptane followed by evaporation of the solvent. N,N-Dimethylformamide dimethylester (DMFDA) is a rapid methylating agent, which provides quantitative yields upon mixing in a nonaqueous solvent with the sample of interest (Table 1, reagent 2). Carboxylic acids are converted to methyl esters, thioles to thioethers, and phenols to methyl ethers. Primary amines are converted into their N,N-dimethylenoethylene derivatives and amino acids are simultaneously modified as this derivative at the amino group and as the methyl ester at the carboxyl group. Aliphatic hydroxy groups are not methylated. Ethyl, propyl, n-butyl, and i-butyl acetics may be used analogously.

Alternatively methylation of active functional groups can be done using methyl iodide (CH3I) or diazomethane (CH2=N+=N−). Sixteen diuretics such as amiloride and hydrochlorothiazide were extracted from urine and then reacted with methyl iodide at 70 °C for 2 h to form methyl derivatives. Short columns and high flow rates permitted analysis times by GC/MS of less than 4 min. Carbamazepine, diclofenac, and ibuprofen were methylated

using diazomethane and determined by GC/MS down to 10 ng L⁻¹, while sulfamethoxazole and its metabolites were determined by liquid chromatography/mass spectrometry (LC/MS).⁵

Pyrolysis of a quaternary ammonium salt (QUAT) in the presence of the organic analyte can be a convenient methylation procedure.⁷ Upon injection of the QUAT mixed with the drug having a reactive amino, hydroxyl, or carboxyl group into the hot injection port (250–300 °C), the appropriate methyl derivative is formed (Table 1, reagent 4). The derivative is swept onto the analytical column for separation and detection. Trimethylanilinium hydroxide (TMAH) is generally the commercially recommended reagent, but trimethyl(α,α,α-trifluoro-m-toly)ammonium hydroxide can be used at a lower injection temperature, which is important for labile unsaturated fatty acids. This method is particularly good for barbiturates, sedatives, xanthine bases, phenolic alkaloids, and dilantin. Pharmaceuticals such as clofibric acid, ibuprofen, carbamazepine, naproxen, ketoprofen, and diclofenac were identified and quantitated by GC/MS via on-line derivatization using tetrabutylammonium salts with large volume (10 µL) sample injection.⁹

Pentafluorobenzyl bromide (PFB-Br) can convert carboxylic acids, phenols, sulfonamides, and thiols into halogenated derivatives that can be easily detected by electron capture (EC) (Table 1, reagent 3). For carboxylic acids, the reaction is run in an organic solvent in the presence of a base such as a tertiary amine for 5 min at 40 °C. The determination of cannabidiol (CBD) and the internal standard tetrahydrocannabinol in blood plasma involved first derivatization by refluxing a hexane extract with PFB-Br overnight with stirring followed by purification on a Florisil™ column using hexane.¹⁰ A typical EC chromatogram obtained on a packed 5% OV-225 glass column is shown in Figure 1. Although a packed column has limited separation capability, it can handle larger amounts of sample. In addition, because the hexane fraction was evaporated to dryness and reconstituted in a small hexane volume, a detection limit of 50 ng mL⁻¹ of CBD in plasma was possible. A second reported example is the solid-phase extraction (SPE) of 19 pharmaceuticals from samples such as sewage, surface, ground, and drinking water. Prederivatization of these pharmaceuticals with PFB-Br before GC/MS was slightly more effective than silylation chemistry (explained in Section 3.3).¹¹ Detection limits down to 1 ng mL⁻¹ were possible. Alternatively, tertiary amines have been derivatized with pentafluorobenzyl chloroformate prior to GC with EC detection.¹²

Alkylchloroformates have been utilized for the derivatization of amphetamines, often before solid-phase microextraction (SPME) and GC/MS. Amphetamine and methamphetamine in urine were immobilized on
an Extrelut extraction column as free bases and then derivatized to N-propoxycarbonyl derivatives with propyl chloroformate \((\text{CH}_3\text{(CH}_2)\text{C(O)}\text{Cl})\). A follow-up study by the same authors used SPME to concentrate the same N-propoxycarbonyl derivatives from the vial headspace before GC. Calibration curves were linear from 0.5 to 50 mg L\(^{-1}\). A similar approach was used for amphetamine and ephedrine drugs using 2,2,2-trichloroethyl chloroformate to convert the compounds to the corresponding carbamates before GC/MS determination using electron impact and chemical ionization approaches. Plasma, urine, and hair samples were analyzed and detection limits were from 2 to 5 ng mL\(^{-1}\) for the biological liquids and in the 0.1-0.2 ng mg\(^{-1}\) range for hair. After conversion of amphetamines to their free base using triethylamine, an SPME fiber coated with an alkylchloroformate was used to sample the headspace and cause derivatization. More conventionally, alkylchloroformate derivatization of cocaine and two derivatives was done before SPME and GC/MS analysis. Detection limits in human hair of 0.1–0.5 ng mg\(^{-1}\) were similar to those reported in reference 16.

Ethyl chloroformate activated \((R)(+)-l\)-phenylethylamide of \(R\) and \(S\) naproxen and desmethylnaproxen enantiomers before GC separation within 11 min on a 5% phenyl-95% methylsiloxane stationary phase. Using the chiral derivatizing agent \((S)(-)-N\)-trifluoroacetyl-L-prolyl chloride (L-TPC) to modify the amine group, resolution at 2.0 of enantiomeric amphetamines was possible with good linearity by GC/MS to 45 ng mL\(^{-1}\).

### 2.2 Acylation

Acylation is the conversion of carboxylic acids, thiols, or amines (compounds that have active OH, SH, and/or NH moieties) into esters, thioesters, and amides, respectively. Acyl derivatives, even geometric isomers, tend to undergo mass spectrometry (MS) fragmentation that leads to useful structural information and differentiation. Perfluoroacylimidazoles such as trifluoroacetylimidazole (TFAI), pentafluoropropionylimidazole (PFAI), or heptafluorobutylimidazole (HFBI) can react with hydroxyl groups and primary or secondary amines to generate the halogenated derivative and the relatively inert by-product imidazole (Table 2, reagent 1). Generally, the reaction times are 1–3 h at 75°C. Indoleamines and indole alcohols, which are acid-sensitive compounds, have been modified by this procedure. Metoclopramide, an antispasmodic agent related to procainamide, has been derivatized with HFBI for GC with EC detection. These reagents are often used in bifunctional derivatization schemes involving silylation chemistry. For example, phenolic amines can be silylated with \(N\)-trihexylsilylimidazole (TMSI) to protect the hydroxyl group and acylated to protect the amine group. Other halogenated imidazoles such as \(p\)-bromobenzyl- and \(p\)-chlorobenzylimidazole have been used because the detectability of the derivatives can be enhanced using EC. However, the volatility and stability of the derivatives under GC conditions tend to be lower compared to the fluorinated types.

\(N\)-Methylbistrifluoroacetamide (MBTFA), shown in Table 2 as reagent 3, permits trifluoroacetylation of primary or secondary amines and carbohydrates under mild nonacidic conditions. For carbohydrates, a single derivative for mono-, di-, tri-, and tetracilla-rides was obtained. The \(N\)-methyltrifluoroacetamide by-product is stable and volatile, being compatible with GC. After extraction with \(t\)-butyl methyl ether and SPE, amphetamines have been derivatized with MBTFA and separated on a 5% phenylmethylsilicone column. On-line flash injection of extracted amphetamines with MBTFA provided GC/MS separation and identification of 12 compounds at limits of detection of 2.5–6.9 ng mL\(^{-1}\).

Perfluoro acid anhydrides \([\text{R}'(\text{C} (=\text{O}))\text{O(\text{C}=\text{O})R]}\), such as trifluoro-, pentafluoro-, and heptafluorooctyl acid anhydride (TFAA, trifluoroacetic anhydride; PFAA, pentafluoropropionic anhydride; HFAA, heptafluorobutyric anhydride) react readily with alcohols, phenols, and urine for the preparation of perfluoroacyl derivatives, which are particularly useful for EC detection (Table 2, reagent 2). Triethylamine is added, as part of the reaction mixture, to neutralize the acidic by-products and drive the reaction to completion. Drugs of abuse are often derivatized in this way before GC/MS confirmation.
A GC/MS example of derivatization of amphetamine and methamphetamine by HFAA is shown in Figure 2(a) and (b). The splitting of the peaks is due to the presence of deuterated internal standards. Excess HFAA, which causes a high background level, column contamination, and eventual degradation of the stationary phase, was removed by the procedure outlined below. The drugs of interest were extracted from 2 mL of urine by SPE columns with a 10% 2-propanol in a chloroform elution solvent. Sodium periodate oxidation of interfering drugs was carried out if necessary. The extract was acidified with 10% HCl in methanol before evaporation and reconstitution of the residue in hexane with 0.1-M trimethylamine. HFAA was added and the mixture was heated in a sealed tube for 1 h at 70 °C. After cooling, deionized water was added to the tube, the tube shaken, and the aqueous phase discarded. A 4% ammonia solution was shaken with the remaining hexane volume and then the organic layer removed for injection into the GC/MS system. The limit of quantification and limit of detection were both on the order of 50 ng mL$^{-1}$ and the linearity was observed up to at least 4000 ng mL$^{-1}$. Newer, but similar, approaches using HFAA for the derivatization of amphetamines and derivatives in biological samples use novel sample preparation methods. Examples of such methods are mixed mode reversed phase-ion exchange SPE prior to derivatization, SPME with derivatization using a polydimethylsiloxane fiber, and extraction with toluene containing HFAA.

An important application of PFAA and HFAA derivatization involves the MS differentiation of substituted methamphetamine or phenethylamine isomers from the controlled drug 3,4-methylenedioxymethamphetamine (3,4-MDMA or Ecstasy). Without derivatization, the MS spectra for these GC-separated isomers are virtually identical to that of 3,4-MDMA. Acylation of the NH or NH$_2$ functional group present in all these compounds with either PFAA or HFAA lowers the basicity of the amine, which allows other fragmentation pathways to occur, resulting in clear distinguishing MS spectra.
Amphetamines, using 2% acetic anhydride, were converted to primary and secondary amides upon injection of the sample solution and furan was used as the reagent for chemical ionization MS to improve selectivity.\(^{37}\)

## 2.3 Silylation

Silylation is the most widely used derivatization scheme for GC. Active hydrogens from acid, alcohol, thiol, amine, and amide groups can all be protected, usually with trimethylsilyl (TMS) groups. The ease of silylation of these functional groups can be ordered: alcohol > phenol > carboxylic acid > amine > amide. Steric hindrance is also a factor within a class of organic compounds. For alcohols, the reactivity order is primary > secondary > tertiary, and, for amines, primary > secondary. Trimethylchlorosilane (TMCS) is the simplest reagent that can be used, often to derivatize carboxylic acids (Table 3, reagent 1). TMCS is often used in conjunction with hexamethyldisilazane (HMDS) (Table 3, reagent 2) to improve the silylation of sugars and related compounds. In general, silylation reagents are unstable and must be protected from moisture. Because an excess of the silylating agent is used in the derivatization reaction to minimize the problem of moisture or other acidic components in the sample, it is recommended that the excess silylation reagent be evaporated using a stream of nitrogen before injection of the sample into the GC column. This avoids several problems such as large reagent blank peaks in the chromatogram and fouling of the flame ionization detector by SiO\(_2\) deposits. A polar stationary phase such as poly(ethylene glycol) (Carbowax\textsuperscript{\textregistered} 20 M) or free fatty acid phase is derivatized by excess silylation reagent and cannot be used.

Silylacetamides are represented in the most popular group of silylation agents, owing to their ability to react quickly and quantitatively under mild conditions. \(N,0\)-Bis(trimethylsilyl)acetamide (BSA) is a highly reactive TMS donor (Table 3, reagent 3). \(N,0\)-Bis(trimethylsilyl)trifluoroacetamide (BSTFA) (Table 3, reagent 4) has the advantage of giving a more fluorinated by-product than BSA. This permits derivatization of lower molecular weight analytes without potential overlap of the trifluoroacetamide by-product.

Cannabinol derivatives were volatilized using the BSTFA reaction and then microextracted from the headspace before GC/MS.\(^{38}\) Limit of detection values ranged from 0.01 to 0.02 ng mg\(^{-1}\). The addition of TMCS to BSTFA promotes the derivatization of amides, secondary amines, and hindered hydroxyl groups. A comprehensive article on drug detection methodology describes the determination of cocaine, heroin, and metabolites in hair, plasma, saliva, and urine samples after isolation by SPE and subsequent derivatization with.

Comparable approaches using TFAA for derivatization of phenylalkylamines such as methamphetamine\(^{31}\) and others including phenteramine, cathinone, and mescaline\(^{32}\) or ketamines\(^{33}\) and subsequent GC/MS have been reported. Human metabolism of ephedrines including ephedrine and phenylpropanolamine was generally found to be low based on TFAA derivatization and GC/MS results.\(^{34}\) Piperazine drugs and their metabolites were separated by LC/MS after SPE and forensic confirmation was made by GC/MS of their TFAA derivatives.\(^{35}\)

The use of nonfluorinated anhydrides is less common. After derivatization with acetic anhydride in the presence of KHCO\(_3\), six serotonin uptake inhibitors such as venlafaxine and fluvoxamine were extracted with a polydimethylsiloxane-divinyl benzene microextraction fiber for 30 min before GC/MS determination.\(^{36}\) Amphetamines, using 2% acetic anhydride, were

\(^a\) TMCS, trimethylchlorosilane; HMDS, hexamethyldisilazane; BSA, \(N\cdot O\)-bis(trimethylsilyl)acetamide; BSTFA, \(N\cdot O\)-bis(trimethylsilyl)trifluoroacetamide; MSTFA, \(N\)-methyl-\(N\)-trimethylsilyltrifluoroacetamide; TMSI, \(N\)-trimethylsilylimidazole.

BSTFA with TMCS before analysis by GC/MS.\(^{39}\) After spiking the plasma, saliva, and hair extracts with internal standards, they were passed through SPE columns and the drugs eluted with a methylene chloride-2 propanol-ammonia solvent. The eluent was evaporated to dryness, reconstituted with acetonitrile, and allowed to react with a BSTFA/TMCS mixture at 60°C for 30 min before analysis by GC/MS. Representative chromatograms are shown in Figure 3(a–c). Separations were affected on a relatively short 12 m \(\times\) 0.2 mm i.d. capillary column. The limit of detection for the analyte was about 1 ng mL\(^{-1}\) in urine, saliva, and plasma and 0.1 ng mg\(^{-1}\) in hair. A BSTFA/TMCS mixture was also shown to be effective for derivatization of the opioid analgesic
buprenorphine in association with benzodiazepines, as well as cocaine and derivatives before GC/MS. Seven diverse pharmaceuticals including caffeine, estradiol, ibuprofen, ketoprofen, musk ketone, naproxen, and triclosan were also more effectively derivatized using the BSTFA + TMCS combination as compared to TMSI.  

N-Methyl-N-trimethylsilyl-trifluoroacetamide (MSTFA) has similar donor strength to BSA and BSTFA but generates an even more volatile by-product, N-methyltrifluoroacetamide (Table 3, reagent 5). Both, excess MSTFA and the by-product, often elute with the solvent peak, eliminating the presence of extra peaks in the chromatogram. Cocaine and its metabolites, benzoylecgonine and eugonine methyl ester, were sequentially derivatized first with methyl iodide to obtain the ester derivative and then MSTFA to form the o-TMS derivative. The derivatized compounds were separated by GC using a methylphenylsilicone column and nitrogen–phosphorus detection. Again, TMCS can be added to MSTFA to promote the derivatization of amides and hindered amines and hydroxyl groups. After SPE, acidic pharmaceuticals such as salicylate, ibuprofen, naproxen, ketoprofen, and diclofenac, as well as carbamazepin, were derivatized with MSTFA + 10% TMCS and determined by GC/MS at nanogram per milliliter levels in wastewater.

The strongest reagent for silylation of hydroxyl groups is TMSI (Table 3, reagent 6). It does not react with amines or amides and is effective for most steroids, including those with unhindered and highly hindered OH groups. It also reacts quickly and smoothly with carboxyl groups. The carboxylated tetrahydrocannabinol was first isolated from urine using a sulfonated polymer SPE cartridge before derivatization with TMSI to form the TMS derivative that could be detected in the range from 1 to 50 ng.

Silyl imidazole compounds, other than those that derivatize with a TMS group, have also been used in conjunction with GC. Methyltestosterone was derivatized using either the dimethylethylsilyl (DMES)-imidazole or dimethylisopropylsilyl (DMIPS)-imidazole to the corresponding silyl ether derivative. Reaction conditions involve heating at 70 °C for 1 h before removal of the excess reagent by N₂ and reconstitution of the residue in cyclohexane. Because the desired application was the assay of methyltestosterone in bulk powder and tablets, separation on a packed column was adequate in the concentration range 0.1–1.5 mg mL⁻¹ (Figure 4a–c).

Alternatively, N-methyl-N-(1,4-dimethylidimethylsilyl)-trifluoroacetamide (MTBSTFA) derivatizes hydroxyl, carboxyl, thiol, and primary or secondary amine substituents by adding a tert-butyldimethylsilyl (TBDMS) group. These TBDMS derivatives are more stable to hydrolysis than TMS compounds and, when analyzed by GC/MS, a strong M-57 fragment is noted, which can be used to determine the molecular weight of the original compound. These advantages have been demonstrated in...
CHEMICAL REAGENTS AND DERIVATIZATION PROCEDURES IN DRUG ANALYSIS

Figure 4 Typical gas chromatograms of (1) methyltestosterone and (2) norethandrolone as (a) TMS, (b) dimethylchlorosilane (DMCS), and (c) DMIPS derivatives. Note the bulkier derivatives are shifted to a cleaner area in the GC trace. (Reproduced with permission from Ref. 47.)

The determination of short- and long-chain carboxylic acids. A factorial experimental design comparison showed MTBSTFA had a better overall performance than BSTFA for selected pharmaceuticals such as salicylate, ibuprofen, naproxen, propranolol, carbamazepine, and others. Thirty drugs of abuse, including amphetamine-type drugs derivatized with HFAA, benzodiazepines and cannabinoids with MTBSTFA, and buprenoraphine with MSTFA were separated with fast temperature programming and a high flow rate on 30 m \( \times \) 0.32 mm i.d. capillary columns after SPE from 250 \( \mu \)L of human oral fluid. The same authors focused on the rapid separation of MTBSTFA derivatized benzodiazepines and other drugs (18 in all) in 4.40 min using a high initial column temperature, fast temperature programming, a thin stationary phase film thickness, and hydrogen as the carrier gas. Limits of quantitation were from 1 to 100 ng mL\(^{-1}\).

A wide variety of drugs including benzodiazepines, cannabinoids, opioids, antidepressants, antipsychotics, antiepileptics, and others were derivatized using a two-step MTBSTFA, MSTFA reaction sequence and the subsequent \( t \)-butyldimethyl silyl and TMS derivatives were determined by GC/MS. A similar two-step derivatization approach was used for \( \beta \)-adrenoceptor ligands and methyl iodide in potassium carbonate and acetone methylated the diuretics before GC/MS of these mixtures in about 5 min using narrow bore capillary columns. To enhance SPME using a polystyrene–divinylbenzene fiber, phenazone drugs were first acetylated on the nitrogen atom using acetic anhydride but then silylated with MTBSTFA, which removes the acetyl group to enhance GC/MS detection.

Pentafluorophenylmethylsilyl (flophemesyl) derivatives are often generated from steroids by reaction with flophemesylamine at room temperature for 15 min. This is a selective reaction with only primary and secondary hydroxyl groups in steroids reacting in the presence of unprotected ketone groups. GC with EC detection provides detection limits in the nanogram–picogram range. Flophemesyl derivatives also have favorable advantages for GC/MS, producing diagnostic ions that carry more of the current than TMS derivatives.

### 2.4 Sample Handling

Generally, drugs are found in aqueous matrices such as urine and plasma; extraction with an organic solvent is required to isolate the drug in a nonaqueous solvent that is compatible with most derivatization reagents as well as to remove inorganic salts that are not compatible with GC. An alternative approach, direct derivatization, combines the extraction and derivatization steps together. Using this approach for drugs in untreated biological samples prior to GC analysis has the primary advantages of improved extractability of a derivatized polar compound as well as the avoidance of stability problems. Direct derivatization of drugs in untreated biological samples can mean not only derivatization in the sample matrix followed by extraction but also a two-phase reaction where the derivatization takes place in the organic phase while extraction of the analyte is continuing from the aqueous phase. Extractive alkylation has been applied to valproic acid and ketoprofen, in which the tetrabutylammonium ion acted as the anion-pairing agent to pull the compound into the organic phase, where alkylation to generate the methyl or phenacyl derivative was possible. Phenolic compounds such as clioquinol have been determined in an analogous fashion. Acylation involving perfluorinated anhydrides and chloroformates has also been used for the determination of drugs such...
as metanephrine and normetanephrine. Chloroformates can dealkylate tertiary amines to form stable carbamates.

SPME uses a fiber, usually fused silica coated with a stationary phase, to provide extraction, preconcentration, and sample introduction into a single step. The actual syringe-like device has an outer septum-piercing needle and a plunger that is the fiber. The fiber can be inserted into a liquid sample matrix or the headspace above a solid or liquid sample. Upon equilibrium, analytes of interest are partitioned between the stationary phase of the fiber and the sample matrix or headspace. After analyte preconcentration into the fiber, the syringe device is inserted into the GC injection port where the analytes are thermally desorbed and swept onto the column for separation. For example, endocrine steroid hormones were extracted from biological and environmental samples using a polycarbonate fiber, which was then introduced into the headspace of a BSTFA solution to cause analyte derivatization before insertion into the GC injection port. It has been reported that SPME, using a carboxene/polydimethylsiloxane fiber, can be effective for adsorption of both the fatty acid anlyte and the derivatizing agent phenyltrimethylammonium hydroxide before fiber insertion into the GC injection port where methylation of the carboxylic acid anlytes occurs. The optimum sample–fiber interaction time was 20 min and the linearity of response for octyldecylicarboxylic acid was about 2 orders of magnitude from about $3 \times 10^{-6}$ M. It would seem that this approach could also be applied to some drugs such as naproxen.

3 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

A variety of chemistries can be adopted for either pre- or postcolumn derivatization in conjunction with HPLC because either aqueous or organic solvent compatible reactions are possible. Postcolumn photochemical derivatization has the advantage of instrumental simplicity with no problems of pumping a reagent or detection background from the reagent. Most of the books reviewing fundamental reactions for pre- and postcolumn derivatization chemistry in conjunction with HPLC were published in the 1980s, which appears to have been the most active time for research in this field. Many review articles have focused on postcolumn derivatization with HPLC. Some specific review articles on derivatization chemistry of pharmaceutical compounds with HPLC have also been published. Although the other articles do not try to be comprehensive, Ahuja gave a virtually complete review of the topic up to 1979. Danielson et al. published another fairly complete review covering the period 1979–1987, which is the basis for this part of the article. Again, a specific example and an overview for each major class of pharmaceutical compounds are given.

3.1 Alkaloids

Separation of atropine and ergotamine by normal-phase liquid chromatography (LC) followed by postcolumn ion-pair extraction with an aqueous solution of 9,10-dimethoxyanthracene-2-sulfonate has been reported. The organic mobile phase was monitored fluorimetrically with detection limits of 40–100 ng. Conversely, methadone, phencyclidine, and their metabolites were separated by reversed-phase HPLC using 9,10-dimethoxyanthracene-2-sulfonic acid in the mobile phase. The resultant ion pairs (Table 4, reagent 3) were extracted with chloroform postcolumn on-line and detected fluorimetrically with detection limits of $1–6 \times 10^{-11}$ M. A precolumn ion-pair derivatization method for atropine, hyoscynamine, scopalamine, and ergotamine, involving picric acid and normal-phase chromatography, provided ultraviolet (UV) detection limits of about 200 ng. Morphine, which can be oxidized to the dimer pseudomorphine using alkaline hexacyanoferrate (III), has been detected fluorimetrically after this postcolumn reaction. Other opiates, such as normorphine, naborphine, codeine, norcodeine, and others, were also reactive. The excitation and emission wavelengths were 323 and 432 nm respectively. The mobile phase, a 12.5:87.5 methanol–0.1 M KBr solution, was propelled through a $C_{18}$ reversed-phase column. The derivatizing agent was 50 mg of $K_3Fe(CN)_6$ in 250 mL of 4 M ammonia solution delivered at 0.4 mL min$^{-1}$. The selectivity advantage of fluorescence over UV detection for the determination of morphine in urine and serum samples was definitive using the instrumentation shown in Figure 5. Morphine could be determined at the $2–30 \mu g \text{ mL}^{-1}$ level in such biological samples with detection limits of about 10 ng. Fluorescence detection of morphine and related opiates was improved about twofold after postcolumn derivatization with alkaline hexacyanoferrate(III) and micelle formation with the nonionic surfactant Triton X. The heroin metabolite 6-acetylmorphine has been determined in urine by reversed-phase HPLC with fluorescence detection after automated precolumn oxidation with hexacyanoferrate(III) at a reported detection limit of 1 ppb. Reserpine, an antihypertensive agent, was detected fluorimetrically after postcolumn reaction with nitrous acid and UV irradiation. Using

this UV photochemical reaction, a 20-fold increase was found in the signal over the native fluorescence of reserpine.

Physostigmine, an acetylcholinesterase inhibitor, was separated from its degradation products and reacted with coulometrically generated bromine. Electrochemical detection of unreacted bromine was inversely proportional to the amount of drug, and a detection limit of 0.5 ng could be attained. An on-line photochemical reaction detector caused decreased fluorescence of ergot alkaloids, permitting the identification of these compounds in complex chromatograms. A similar system has been shown to convert cannabinol into a fluorescent derivative, providing detection limits of less than 1 ng in urine. The use of this approach was extended for the detection of four Cinchona alkaloids and their dihydro derivatives as well as pyridoxine (vitamin B6) after isocratic reversed-phase separation. On-line reaction of cannabinoids with fast blue salt B produced colored derivatives for detection at 490 nm. Pilocarpine was quaternized with p-nitrobenzyl bromide before reversed-phase HPLC separation and detection at 254 nm.

### 3.2 Amines

Primarily, fluorescent methods have been developed for amino acids and peptides. The o-phthalaldehyde (OPA), mercaptoethanol (or other thiol) reaction (Table 4, reagent 1) has been studied in both pre- and postcolumn modes; specific articles describing such chemistry with common amino acids are cited in general references. Other amino acids such as o-carboxymethyl-L-cysteine, baclofen, melphalan and debrisoquine and its hydroxy metabolites was possible by reaction through the guanidine moiety to form fluorescent compounds. A postcolumn photochemical reactor caused the cleavage of methotrexate to form the highly fluorescent 2,4-diaminopteridine-6-carboxaldehyde. Indoleamines were condensed with an aldehyde or o-keto acid to form fluorescent carboline derivatives.

### 3.3 Drugs

\(\gamma\)-Aminobutyric acid was modified with dansyl chloride before reversed-phase HPLC and fluorescent detection. Detection at 360 nm was possible for N-acetylcysteine after reaction with 2,4-dinitro-1-fluorobenzene. 1,2-Diamino-4,5-dimethoxybenzene was used to form a fluorescent derivative of p-hydroxybenzoin. A review of precolumn derivatization methods targeting only amino acids is available. The peptide leupeptin was reacted through the guanidine moiety with benzoin to form a fluorescent derivative. Felypressin, a nonapeptide, was derivatized with fluorescent methods targeting only amino acids is available. An ion-pair detection technique has been applied to hydrophobic amino acids and peptides.

A variety of other fluorescent methods have also been reported for specific drugs. Tranexamic acid has been detected using OPA. Biogenic amines such as tyramine, tryptamine, and serotonin were reacted with OPA in a post-mode. The OPA precolsumn fluorescent reaction has also been applied to L-buthionine-(S,R)-sulfoximine in plasma and mexiletine. Fluorescent derivatization with fluorescamine has been applied in the postcolumn mode for sulfapyridine as well as in the precolumn mode for tocinamide and the antiepileptic drugs vigabatrin and gabapentin. Enantiomers of mexiletine have also been resolved. After conversion of the drug panthenol to aminopropanol, the fluorescamine reaction provided detection limits of 0.4 µg. The determination of debrisoquine and its hydroxy metabolites was possible by reaction through the guanidine moiety to form fluorescent compounds. A postcolumn photochemical reactor caused the cleavage of methotrexate to form the highly fluorescent 2,4-diaminopteridine-6-carboxaldehyde. Indoleamines were condensed with an aldehyde or o-keto acid to form fluorescent carboline derivatives. The determination of debrisoquine and its hydroxy metabolites was possible by reaction through the guanidine moiety to form fluorescent compounds. A postcolumn photochemical reactor caused the cleavage of methotrexate to form the highly fluorescent 2,4-diaminopteridine-6-carboxaldehyde. Indoleamines were condensed with an aldehyde or o-keto acid to form fluorescent carboline derivatives.
was determined by reversed-phase C_{18} silica LC with a limit of quantification of 2 ng mL\(^{-1}\) in human serum.\(^{(131)}\)

Some UV derivatization methods have been developed for aliphatic and even aromatic amines. Phenylisothiocyanate (PITC) has been used as a precolumn derivatizing agent for amino acids in conjunction with reversed-phase HPLC. Both primary and secondary amines can react with PITC (Table 5, reagent 1(B)) and the aromatic tag provides good retention for the smaller amino acids.\(^{(132)}\) Both primary and secondary amines were derivatized with 9-fluorenymethyl chloroformate (FMOC) before separation by reversed-phase HPLC with UV detection at 254 nm. After SPE of a urine sample, β-phenethylamine was determined with a detection limit of 0.1 ng mL\(^{-1}\).\(^{(133)}\) Amphetamine and methamphetamine have been reacted with 4-methoxybenzoyl chloride (Table 5, reagent 1(A)) and other acid chlorides for subsequent UV detection.\(^{(134)}\) A comparison of methods for amphetamines has been made.\(^{(135)}\) The enantiomeric separation of (−)-1-(9-fluorenyl)ethyl chloroformate chiral derivatives of primary and secondary amphetamines was possible either by UV or fluorescence detection with resolution ranging from 0.9 to about 2.\(^{(136)}\) The cardiotonic drug heptaminol has been derivatized with aminoazobenzene-4-isothiocyanate for UV detection at 420 nm\(^{(137)}\) or OPA for electrochemical detection.\(^{(138)}\) Secondary amines, such as piperazines, were converted into UV derivatives with \(m\)-toluoyl chloride.\(^{(139)}\) Enantiomers of metoprolol have been separated after reaction with the chiral reagent \((S)-(−)-phenylethyl isocyanate.\(^{(140)}\) The determination of isophenindamine in the presence of phenindamine

tartrate has been achieved by forming charge transfer complexes using AgNO3 and reversed-phase HPLC. Antihistamines and other pharmaceuticals with a tertiary amine moiety have been derivatized to provide for luminescence detection. An ion-pair extraction detector using dimethoxyanthracene sulfonate (Table 4, reagent 3) has permitted the fluorescent determination of tertiary amines, such as brompheniramine and chlorpheniramine, ephedrine, and hyoscyamine, with detection limits of 200–500 pg. Precolumn reaction of chlorpheniramine with benzyl chloroformate gives a fluorescent derivative with a detection limit of 0.1 ng mL−1. Antihistamines, such as diphenhydramine, were converted through the tertiary amine group into fluorescent derivatives using 2-naphthyl chloroformate. Aliphatic tertiary amines can be determined at the picomole level by postcolumn chemiluminescent detection, using tris(bipyridyl)ruthenium(III). This topic of postcolumn electrochemiluminescence detection has been reviewed for both LC and CE. Antihistamines in urine have also been separated by HPLC and detected with good selectivity using this ruthenium metal complex (Figure 6a–c). Tamoxifen and its metabolites in human serum can be UV photochemically activated to form fluorescent phenanthrenes. Postcolumn UV irradiation of tamoxifen and its derivatives caused rearrangement to a substituted phenanthrene, permitting fluorescent detection with 0.1 ng mL−1 detection limits. Several analgesic compounds such as phenazone, propylnaphthazine, and dimethylaminophenazine, as well as their metabolites, were derivatized in situ with acetic anhydride to make more hydrophobic compounds that could be isolated from the sample matrix using SPE, before their separation by LC/MS/MS.

Derivatives of nicotine, cotinine, and other metabolites in urine after HPLC separation can be detected at 530 nm by using diethylthiobarbituric acid as a color-forming agent. Nicotinic acid and niacinamide were derivatized through the heterocyclic nitrogen using cyanogen bromide and then an arylamine to give polymethylene dyes, which were separated by micellar LC. DL-Carnitine and acetyl-DL-carnitine were reacted with ruthenium metal complex (Figure 6a–c). HPLC and detected with good selectivity using this chemiluminescence detection. (Reproduced with permission from Ref. 151.)

Figure 6 Chromatograms of an undiluted urine sample spiked with (A) 0.15 µg mL−1 pheniramine, (B) 0.26 µg mL−1 brompheniramine, and (C) 0.09 µg mL−1 diphenhydramine taken with (a) UV (214 nm), (b) UV (254 nm), and (c) Ru (bpy)32+ chemiluminescence detection. (Reproduced with permission from Ref. 151.)

Figure 6 Chromatograms of an undiluted urine sample spiked with (A) 0.15 µg mL−1 pheniramine, (B) 0.26 µg mL−1 brompheniramine, and (C) 0.09 µg mL−1 diphenhydramine taken with (a) UV (214 nm), (b) UV (254 nm), and (c) Ru (bpy)32+ chemiluminescence detection. (Reproduced with permission from Ref. 151.)

Derivatives of nicotine, cotinine, and other metabolites in urine after HPLC separation can be detected at 530 nm by using diethylthiobarbituric acid as a color-forming agent. Nicotinic acid and niacinamide were derivatized through the heterocyclic nitrogen using cyanogen bromide and then an arylamine to give polymethylene dyes, which were separated by micellar LC. DL-Carnitine and acetyl-DL-carnitine were reacted with (a-bromo)methylphenyl ketone to form chiral derivatives that were separated on a chiral LC column to determine the enantiomeric purity of the L form. Racemic phenothiazines were N-demethylated with vinyl chloroformate to form their secondary amines, which could then be reacted with (R)-(−)-1-phenylethyl isocyanate (Table 5, reagent 3), and these compounds were separated by reversed-phase HPLC. Tertiary tetrahydroisoquinolines, such as diclofensine, were oxidized before photochemical conversion to fluorescent isoquinolinium derivatives. After postcolumn ion-pair extraction of secoverine, peroxylate chemiluminescence (CL) detection was carried out.

Postcolumn detection of platinum(II) antineoplastic agents such as cisplatin is possible, as shown in Figure 7. The cisplatin-derived species are first reacted with an oxidant such as dichromate to form an activated species, which then combines rapidly with bisulfate to give a UV-absorbing complex. Using knitted open-tubular reactors, delay times of 26 s for the dichromate reaction and 4.7 min for the bisulfate reaction were found to be optimal. Figure 8(b) shows the substantial improvement in absorbance response of the separated derivatives as compared to the detection (Figure 8a) of the unmodified platinum compounds. Detection limits of 5–10 µg mL−1 were possible. Cisplatin was also determined in a plasma ultrafiltrate sample at the 5-ng level.

3.3 Antibiotics

This class of pharmaceuticals has received major attention for both pre- and postcolumn derivatization. Fluorescent derivatization of the primary amine group of
CHEMICAL REAGENTS AND DERIVATIZATION PROCEDURES IN DRUG ANALYSIS

Figure 8 Comparison of UV detection (300 nm) after HPLC separation (a) and reactor response (290 nm) to derivatized platinum (b) for a mixture of cis-dichloroplatinum complexes: (1) cis-dichloro(1,2-diaminocyclohexane)platinum(II), (2) cis-dichloro(ethylenediamine)platinum(II), and (3) cis-dichlorodiammineplatinum(II). (Reproduced with permission from Ref. 161.)

many antibiotics with OPA and a sulphydryl compound, often mercaptoethanol, has been commonly performed (Table 4, reagent 1). Gentamicin, penicillin V, after enzymatic conversion to 6-aminopenicillanic acid, penicillin N, cephalosporin C, cycloserine, and fludalanine were assayed by using an OPA postcolumn reactor. Spectinomycin, after postcolumn oxidation with hypochlorite, could also be derivatized with OPA in a second reaction coil. Reversed-phase separation was employed for all these separations because the OPA reaction is carried out in an alkaline buffer solution. Precolumn reactions with OPA for gentamicin, sisomicin, and phosphinothricin and its alanine analog before reversed-phase separation have all been reported. Amikacin isomers were first adsorbed on a silica gel column before reaction with OPA; the derivatives were eluted with ethanol before separation by reversed-phase HPLC. A comparison of pre- and postcolumn OPA reaction conditions for gentamicin has been made. For all these OPA fluorescence methods, detection limits are about 1 µg mL⁻¹. For example, β-lactams found in microbial fermentation broths were separated on a C₁₈ HPLC column and detected fluorimetrically with excitation at 350 nm and emission at 450 nm after reaction with OPA and mercaptoethanol. Cephapirin, penicillin N, cephalosporin C, and 6-aminopenicillanic acid were separated in about 12 min at a flow rate of 1.5 mL min⁻¹ with postcolumn conditions involving the OPA reagent at pH 12, a reaction coil of 12 m, a temperature of 90 °C, and a reagent flow rate of 0.8 mL min⁻¹. Detection limits of less than 0.5 and 1.0 µg mL⁻¹ were achieved for penicillin N and cephalosporin C respectively.

Numerous other postcolumn UV, fluorimetric, and electrochemical methods have been reported for tetracycline-type antibiotics and related compounds. Formation of a mercuric mercaptide of penicillins permits UV detection at 310 nm with detection limits of 10 ng. Sulfonamides in egg, milk, and meat samples have been detected at 450 nm after derivatization with p-dimethylaminobenzaldehyde. Monensin, narasin, and salinomycin in animal feeds have been reacted with vanillin to give products detectable at 520 nm. Penicillins, such as amoxicillin, ampicillin, and others, can be separated by reversed-phase HPLC with alkaline degradation in the presence of mercuric chloride (Table 5, reagent 6). Methanol promotes this reaction, forming the ring-cleaved product, which absorbs at 274 nm, and is detectable at 50 ng mL⁻¹. It was discovered later that sodium hypochlorite could replace the mercuric chloride reagent while maintaining a 1-min hydrolysis time. Application of this latter method to penicillins in biological samples has been made. Fluorescent detection of streptomycin reacted through the guanidino groups with naphthoquinone-4-sulfonate in alkaline solution has been reported in serum samples. Photothermal derivatization of ciprofloxacin and its metabolites permits fluorescent detection throughout a linear range of about 2–1000 ng mL⁻¹.
Photolysis with electrochemical detection of penicillins and cephalosporins has provided detection limits of about 6 ng.\textsuperscript{(185)} Tetracycline, oxytetracycline, chlorotetracycline, demeclocycline, doxycycline, and mecloxycline were separated on a C\textsubscript{18} column and then photoradiated before chemiluminescent detection with rhodamine and cerium(IV).\textsuperscript{(186)} Detection limits in the 0.1–0.3 ng mL\textsuperscript{−1} range were reported. Electrochemically generated bromine was used as an oxidizing agent for cephalosporins and their decomposition products.\textsuperscript{(187)} The excess bromine was detected at 0.4 V using a glassy carbon electrode. A comparison of this method with UV detection and postcolumn fluorescamine derivatization has recently been summarized.\textsuperscript{(188)} Acidification of a serum sample sometimes improved recovery of cephalosporins when micellar chromatography was used with sodium dodecyl sulfate (SDS) in the mobile phase.\textsuperscript{(189)} Fluorescamine has been used in an automated system for amoxycillin in biological fluids.\textsuperscript{(190)} CL detection of clindamycin phosphate using tris(bipyridyl)rhodium(III)\textsuperscript{(191)} gave detection limits of 8 ppb compared to 970 ppb using UV detection at 214 nm.

A variety of reagents are also available for precolumn derivatization of antibiotics and UV or fluorimetric detection. Phenacyl esters of some natural penicillins were prepared using dibromooctophenone before reversed-phase HPLC with UV detection.\textsuperscript{(192)} Nitrobenzene derivatives of neomycin B and C can be separated by normal-phase HPLC and detected at 350 nm.\textsuperscript{(193)} Similar methods using 1-fluoro-2,4-dinitrobenzene to form 2,4-dinitrophenyl derivatives of neomycin B and C\textsuperscript{(194,195)} and amikacin\textsuperscript{(196,197)} have also been published. Neomycin and other aminoglycosides have been converted to benzoyl derivatives before UV detection at 230 nm.\textsuperscript{(198)} Aminoglycosides have also been reacted with 2,4,6-trinitrobenzenesulfonic acid, permitting UV detection at 350 nm.\textsuperscript{(199)} Ion-pair formation of methscopolamine bromide with an aromatic anion during reversed-phase HPLC permitted UV detection.\textsuperscript{(200)} The secondary amine group of spectinomycin was derivatized with 2-naphthalenesulfonyl chloride (Table 5, reagent 2) before normal-phase HPLC and UV detection at 254 nm.\textsuperscript{(201)} Nitrofurantoin drugs furazolidone, nitrofurazone, furaladone, and nitrofurantoin were hydrolyzed and the released side chains derivatized with 2-nitrobenzaldehyde before SPE and determination by LC/MS with atmospheric chemical ionization.\textsuperscript{(202)} Nitrofurantoin antibiotics and metabolites in honey were also determined as 2-nitrobenzaldehyde derivatives by LC/MS/MS and the predominant compound was found to be furazolidone.\textsuperscript{(203)}

The reagent FMOCS formed fluorescent derivatives of natural penicillins, cephalosporins, and their precursors in biological samples.\textsuperscript{(204)} β-Lactams were prederivatized with FMOCS for 5 min at 20°C in a borate buffer at pH 7.7 before injection of the derivatives onto a C\textsubscript{18} reversed-phase column. Excitation and emission wavelengths for the fluorescent detection were 260 and 313 nm respectively. A typical chromatogram is given in Figure 9, showing the modest acetonitrile gradient until after elution of ampicillin in which the acetonitrile is taken to 100%. Detection limits were 0.01 and 0.05 µg mL\textsuperscript{−1} for 6-aminopenicillanic acid and isopenicillin N, respectively. Application of the method to fermentation broths was made over a range of 0.05–100 µg mL\textsuperscript{−1}. A maleimide reagent gave a fluorescent derivative for penicillin.\textsuperscript{(205)} An imidazole–mercuric chloride reagent can convert penicillins into mercury stabilized penicillanic acids after reaction at 50°C for 50 min prior to UV detection at 325 nm.\textsuperscript{(206)} A comparison of this method with the postcolumn OPA fluorescence method has been made.\textsuperscript{(207)} A similar method using 1,2,4-triazole and Hg(II) for ampicillin, amoxicillin, and other antibiotics has been studied.\textsuperscript{(208–210)} Two precolumn derivatization studies with UV detection were checked with real samples. Tobramycin plus the impurities neamine and kanamycin and also the degradation product nebramine were derivatized with 2,4-dinitrofluorobenzene for 20 min at 70°C in 0.8-mM sulfuric acid. Separation of the derivatives on a C\textsubscript{18} column with detection at 365 nm was carried out, and the stability of tobramycin in ophthalmic solutions was determined.\textsuperscript{(211)}

![Figure 9](image_url)
3.4 Barbiturates

Precolumn methods primarily include reaction with various alkylation reagents. The highly reactive chlorine of N-chloromethylphthalimides permits derivatization of OH and NH functional groups to form UV-absorbing compounds. Detection limits of 5 ng for phenobarbital have been reported.

2-Naphthacyl bromide forms strongly absorbing derivatives of barbiturates at 254 nm with detection in plasma or serum below the therapeutic range. An online solid-phase anion-exchange extraction provided enhanced chromatographic selectivity of barbiturates in urine. Postcolumn UV detection of barbiturates can be conveniently enhanced by mixing with a pH 10 borate buffer. A wavelength shift for maximum absorbance from 220 to 240 nm provides for detection limits of about 6 µg for butabarbital.

The UV detection of barbiturates can be significantly enhanced through postcolumn photochemical derivatization. Barbiturates have no significant absorbance above 230 nm and detection in the 200–220 nm range can be complicated by the presence of interfering peaks, particularly in biological samples such as serum. Using a 25 mm × 0.25 mm i.d. Teflon-knitted open-tubular reactor mounted around a mercury lamp, which provided an irradiation time of about 190 s, excellent signal enhancement at 270 nm was possible for barbiturates (Figure 10a and b). It was determined by HPLC that dealkylation at the 5-position to give ethylbarbituric acid was the mechanism of the photochemical reaction.

3.5 Carbonyl Compounds and Carboxylic Acids

First, a short summary of the methods involving the reduction of quinone compounds to form fluorescent hydroxy derivatives is given. Vitamin K₃ in human plasma was electrochemically reduced at −0.4 V and the fluorescent derivative detected at levels as low as 25–50 pg. A comparison of this method with UV and electrochemical oxidation detection systems has been made. Danthron (1,8-dihydroxyanthraquinone) has been reduced with dithionite and determined by either flow injection analysis in Modane tablets or HPLC in urine. A comparison of UV and fluorescence chromatograms for danthron spiked in a urine sample showed the selectivity advantage of fluorescence (Figure 11a and b). Dansylhydrazine formed fluorescent derivatives of tetraphenylacetone isomers before separation. Short-chain carboxylic acids were modified using p-bromophenacyl bromide (Table 5, reagent 4) to form esters that could be easily detected by UV absorbance.

5-Bromomethylfluorescein was studied for the derivatization of carboxylic acids for detection by either UV absorbance or fluorescence (standard and laser induced). Model analytes included prostaglandins (unsaturated carboxylic acids) and the drug cefuroxime, and also standard aliphatic and aromatic carboxylic acids. Dicarboxylic acids did not react with bromomethylfluorescein, possibly due to solubility problems in the organic reaction medium. Fatty acids and prostaglandins were converted into p-hydroxanilides using p-aminophenol (Table 4, reagent 5). These hydroxy derivatives were then oxidized through electrochemical detection after reversed-phase HPLC. A UV-absorbing naphthacetyl ester of the prostaglandin carboprost has been formed before normal-phase HPLC. Fluorescent derivatives of prostaglandins using 9-anthryldiazomethane provided detection limits of 100 pg after reversed-phase HPLC. The prostaglandin arbabprostil was derivatized with panacyl bromide before column switching using fluorescent derivatization. Oxidation of prostaglandins to the corresponding 15-oxo derivatives using pyridinium dichromate permitted UV detection at 228 nm and picomole detection limits. Prostaglandins have also been derivatized with p-(9-anthryl氧yl)phenacyl bromide. Oxidation of prostaglandins to the corresponding 15-oxo derivatives using pyridinium dichromate permitted UV detection at 228 nm and picomole detection limits. Prostaglandins have been labeled with the fluorescent reagent 9-anthryldiazomethane through the carboxyl group. This esterification reaction can be carried out under mild conditions such as 40°C for 30 min. Five prostaglandin derivatives were separated by reversed-phase HPLC using fluorescent detection with...
excitation at 365 nm and emission at 418 nm at the 8-ng level. Ascorbic acid from 5 to 800 mg L\(^{-1}\) was detected by CL after postcolumn reaction with lucigenin. After derivatization with 1,2-phenylenediamine, both ascorbic acid and dehydroascorbic acid were separated by reversed-phase ion-pair HPLC. The same two compounds were separated by reversed-phase HPLC, and the dehydroascorbic acid was reduced to ascorbic acid with dithiothreitol for UV detection at 267 nm. UV detection of bis(dinitrophenyl)hydrazine derivatives of ascorbic and dehydroascorbic acid was possible at 497 nm. Four forms of ascorbic acid, the previous two plus isoascorbic acid and its dehydro form, were detected postcolumn using benzamidine and fluorescence. Total ascorbic acid was determined fluorimetrically after reaction with diaminodimethoxybenzene.

A number of methods directed toward pain relievers and other compounds with carbonyl groups have been published. Indomethacin formed a fluorescent derivative after postcolumn alkaline hydrolysis, giving a detection limit of 5 pg. Postcolumn alkaline hydrolysis has also been applied to aspirin in plasma in order to form the fluorescent salicylic acid. A wide variety of acidic compounds including acetylsalicylate, ibuprofen, ketoprofen, naproxen, benzaflurate, diclofenac, and tolenamic acid were determined by HPLC with postcolumn photochemical reaction and fluorescence at the 2–120 ng mL\(^{-1}\) level. The enantiomeric composition of ibuprofen in human plasma has been resolved after prederivatization with (S)–(−)-1-phenyl-ethylamine or ethyl chlorofornate–leucinamide. Flunoxaprofen enantiomers have been separated after reaction with (S)–(−)-1-phenyl-ethylamine. Artesunic acid was determined after derivatization with \(o,p\)-nitrobenzyl-N,N’-diisopropylsoura by HPLC with UV detection. Carnitine, betaine, and related compounds have been reacted to form either \(4’\)-bromophenacyl esters or \(p\)-nitrobenzyl oxines to permit UV detection at 254 nm. A new acridinium sulfonamide label permits the chemiluminescent detection of carboxylic acids such as the test compound ibuprofen. This alkylation reaction takes place in dry acetonitrile for 20 min at 50 \(^\circ\)C and separation of the derivatized compound is possible on a C\(_{18}\) column with an acetonitrile–water–tetrahydrofuran mobile phase with the ion-pairing agent tetrabutylammonium ion. CL detection of the acridinium label is possible by postcolumn addition of potassium hydroxide solution. A detection limit of 60 pg of derivatized ibuprofen was found.

The formation of multiple molecular ions from various alkali metals in LC/MS can reduce reproducibility and make sensitive quantitation difficult. The addition of a primary alkylamine to the mobile phase can cause preferential formation of the alkylammonium adduct and suppression of other multiple molecular ions. Octylamine was particularly advantageous in improving the detectability of paclitaxel and docetaxol by about a factor of 4–5 down to about 0.5–1.0 ng mL\(^{-1}\). A similar enhancement was reported for a 3-benzothiepine compound TAK-778 using 1-hexylamine; interaction of the alkyl amine with the phosphoryl group was postulated. Methylammonium acetate was effective in improving the MS sensitivity for simvastin and its hydroxy acid degradation product. Twelve acidic pharmaceuticals and triclosan were determined by ion-pair IC using tri-n-butylamine and electrospray ionization-MS. The ion-pairing agent increased the MS signal intensity, permitting detection limits in the 6–200 ng L\(^{-1}\) range.

### 3.6 Catecholamines

Precolumn fluorescent derivatization of catecholamines with OPA and a thiol has been well established (Table 4, reagent 1). Norepinephrine, dopamine, and normetanephrine have been measured at the low picogram level after reversed-phase HPLC. An
electrochemical cell placed between the injector and the column was used for oxidation of adrenaline and levodopa to the corresponding quinones for detection in the visible region.

Resolution of norephedrine enantiomers after derivatization with either acetylglycosyl isothiocyanates or 4-methyl-5-phenyl-2-oxazolidone has been reported. Fluorescent catecholamine derivatives have been generated using 1,2-diphenylethylenediamine, providing detection limits in the femtomole range.

Postcolumn fluorescent reaction of norepinephrine and epinephrine with trihydroxyindole provided 20–30 pg detection limits. This method was compared with the OPA–thiol reaction in the postcolumn mode. The same two catecholamines can be converted into fluorescent products by heating in an alkaline borate buffer after ion-exchange chromatography. Dopamine isomers in serum and urine have been separated before hydrolysis and reaction with p-aminobenzoic acid to form fluorescent products. Glicyclglycine as an alternative postcolumn reagent to glycinamide increased the rate of formation of fluorescent derivatives after ion-exchange HPLC. Catecholamines catalyze the reaction between formaldehyde and o-dintrobenezene and permit their detection at 560 nm.

### 3.7 Hydroxy Compounds

Most precolumn methods focus on enhancing UV detection. Isotachysterol derivatives of vitamin D improved detection at 290 nm after normal-phase HPLC. On-column periodate oxidation of ephedrine sulfate, a nasal decongestant, to form benzyl alcohol has been carried out in a seven-laboratory study. Indirect photometric detection using n-heptyl p-aminobenzoate in the mobile phase and a C18 column has been applied to menthol. Enantiomers of propranolol and 4-hydroxypropranolol were formed upon derivatization with (+)-1-phenylethyl isocyanate or (+)-tetracetyl β-D-glucopyranosyl isothiocyanate and separated by reversed-phase HPLC. Enantiomers of derivatized or underivatized propranolol have been separated. Diastereomeric derivatization of 1-methyl-3-pyrididinol and proxyphyl ine for UV detection has been accomplished. Qinghaosu, an antimalaria component in a Chinese herb, can be converted into a UV-absorbing compound using a sodium hydroxide solution before HPLC separation. A derivative of qinghaosu has been esterified with diacetyldihydrofluorescein before HPLC and UV detection. Cholic acid and its derivatives have been labeled with 1-anthroylnitrile before HPLC and fluorescent detection at the femtomole level. Tropism has been converted into the corresponding spiro alcohol before fluorescent derivatization with benoxaprofen chloride and reversed-phase HPLC.

Dervatization can be an effective method to facilitate the chiral separation of pharmaceuticals. Nadolol diastereomers were derivatized with (R)-(-)-1-(1-naphthyl)ethyl isothiocyanate to chiral urea derivatives through the secondary amine group by reaction for 5 min at 45 °C. Separation of the RS, SR, RR, and SS diastereomers was straightforward on a C18 column using a 60:40 water–acetonitrile mobile phase. Fluorescence detection with excitation at 285 nm and emission at 340 nm provided selectivity for the determination of nadolol in plasma samples. The limit of detection was 2.5 ng mL⁻¹, representing 50 pg injected. This chiral derivatization method has been used for the determination of enantiomers of other β-blocker drugs.

A few of the postcolumn approaches are outlined below. Using a photochemical reactor, diethylstilbestrol (DES) has been converted into a fluorescent derivative and determined at the low parts-per-billion level in biological matrices. Anabolic stilbenes, such as DES, have been measured in urine by HPLC and an off-line CL immunochemical assay. The antihypertensive agent fenoldopam was formed using a postcolumn enzyme reactor from the corresponding glucuronide, and detected electrochemically. Cycloedextrins in biological fluids were assayed by negative colorimetric detection after postcolumn complexation with phenolphthalein. Vitamin B₆ (pyridoxine) has been postcolumn derivatized with 2,6-dibromoquinone-4-chlorimide to form a colored product with a maximum absorbance at 650 nm.

### 3.8 Steroids

Esterified estrogens were converted into their free phenolic forms by acid hydrolysis, and separation could be achieved by reversed-phase HPLC. The chromatographic behavior of estrogen carbonyls, such as equilenin, equilin, and estrone, was improved upon reduction to the 17α-hydroxy compounds using sodium borohydride. Prederivatization of conjugated estrogens with dansyl chloride permitted fluorescent detection after separation by normal-phase HPLC. This method was modified by having the dansylation prederivatization reaction with the estrogens occur on the SPE column before determination by HPLC with MS/MS detection at the parts-per-trillion level. Ketosteroids, such as androstosterone, dehydroepiandrosterone, epiandrosterone, and etiocholanolone, were derivatized with p-nitrophenylhydrazine (Table 4, reaction 6) and detected electrochemically at levels as low as 200 pg.

Isonicotinoyl hydrazine was used to tag steroids, such as corticosterone, to permit fluorescent detection after normal-phase HPLC. Further work using this
method with reversed-phase HPLC and optimized reaction conditions permitted detection limits as low as 7–10 ng.\(^{294,295}\) 17-Oxosteroids were labeled with dansylhydrazine and then chromatographed on a silica column with subsequent fluorescent detection from 60 to 100 pg.\(^{296}\) A similar method for this class of compounds using 3-chloroformyl-7-methoxycoumarin and reversed-phase HPLC has been published.\(^{297}\) Hydroxysteroids were derivatized with anthroylnitrile, showing the feasibility of the reaction for fluorescent detection after HPLC.\(^{298}\)

Six corticosteroids were separated within 25 min and reacted with a lucigenin–KOH solution for CL detection.\(^{299}\) The reactive site is an α-hydroxycarbonyl group, and detection limits of 2 pg were comparable to those with precolumn fluorescent methods. Corticosteroids were also derivatized postcolumn with glycine in the presence of hexacyanoferrate(III) before fluorimetric detection at the 5-ng level.\(^{300}\) Digoxin, a widely used cardiac glycoside, has been detected fluorimetrically by postcolumn reaction with a solution of ascorbic acid, peroxide, and HCl.\(^{301,302}\) A detection limit of less than 1 ng was attained.

Digoxin and its metabolites, such as digoxigenin, were derivatized with 1-naphthyl chloride before separation and fluorescent detection,\(^{303}\) and 5 ng amounts could be determined in urine or feces. A similar method using 4-nitrobenzoyl chloride has been reported.\(^{304}\) Dihydrodigoxin, a major metabolite of digoxin, has been separated from digoxin with dual UV and postcolumn fluorescent derivatization detection.\(^{305}\) The photoreduction of anthroquinone-2,6-disulfonate to the fluorescent 9,10-dihydroxyanthracene-2,6-disulfonate occurs only in the presence of hydrogen atom-donating substrates, such as alcohols, aldehydes, amines, ethers, and saccharides. Using a knitted Teflon reactor, cardiac glycosides, such as digoxin, digoxigenin, and digimatin, have been determined in the range 50–500 ng.\(^{306}\)

### 3.9 Sulfur Compounds

Most methods employ a precolumn reaction to form fluorescent or UV derivatives. Dansylaziridine\(^{307}\) was used to determine cysteine and other thiols. Biological thiols, such as glutathione and ergothioneine, were reacted with monobromobimane (Table 4, reagent 4) before ion-exchange chromatography.\(^{308}\) This method was also adopted for the determination of dithiols, such as 2,3-dimercaptopropane-1-sulfonic acid, in urine at levels as low as 10 pmol.\(^{309}\) Fluorescent derivatization of 2-mercaptopropionylglycine using N-(7-dimethylamino-4-methyl-3-coumarinyl)maleimide could probably be extended to other thiol compounds.\(^{310}\) Resolution of the optical isomers of diltiazem was accomplished using UV detection after derivatization with optically pure 2-naphthylsulfonyl-2-pyrollidinecarbonyl chloride.\(^{311}\) Three N-substituted maleimides were compared for precolumn derivatization of thiols such as penicillamine before electrochemical detection at the picogram level.\(^{312}\) Ethacrynic acid (Table 5, reagent 5) forms UV-detectable derivatives of thiols, such as captopril, N-acetyl-L-cysteine, and mercaptopropionylglycine with detection limits as low as 0.5 µg mL\(^{-1}\).\(^{313}\)

Postcolumn derivatization of thioethers, such as ampicillin and ranitidine, was accomplished using on-line generated bromine and electrochemical detection of the excess bromine.\(^{314}\) An analogous method has been reported for phenothiazines, such as thioridazine;
however, the resultant products from the oxidation reaction with bromine are detected fluorimetrically.\(^{315}\) Photochemical activation of phenothiazines and demoxepam in 2 min and subsequent fluorescence detection provided detection limits a factor of 10 better than UV detection.\(^{316}\) Applications of photochemical reactors to a variety of pharmaceuticals, such as phenothiazines, have been summarized.\(^{317,318}\) A precolumn derivatization method for phenothiazine involves desulfurization with Raney nickel to produce diphenylamine, which is electrochemically active.\(^{319}\) A detection limit of 10 pg was found. The reagent pyrenemaleimide provided derivatization of \(N\)-acetylcysteine with a detection limit of 10 pmol.\(^{320}\) Postcolumn complexation of disulfiram and two of its metabolites using \(Cu^{2+}\) allowed colorimetric detection at 435 nm with detection limits in the low parts-per-billion range.\(^{321}\) Quenched peroxalate CL has been employed using immobilized reagents in a postcolumn reactor for thioridazin, sulforidazine, and methimazole.\(^{322}\)

On-line precolumn derivatization to improve reproducibility has been demonstrated for the determination of busulfan in human serum. A schematic diagram of the HPLC system is shown in Figure 13; all three columns \(C_1, C_2,\) and \(C_3\) were \(C_{18}\) type with different lengths and/or diameters. After extraction of busulfan from serum, the residue reconstituted in water was injected on to \(C_1\), where it was derivatized with diethyldithiocarbamate (DCC) in mobile phase A for 5 min. Then the busulfan–DCC derivative from \(C_1\) was backflushed on to \(C_2\), where it was separated using mobile phase B. Because the background interference from mostly excess DCC overlapped the busulfan–DCC derivative peak completely, valve 2 was used to take a heart cut of this peak of interest and inject it on to \(C_3\). The resulting separation using mobile phase C is shown in Figure 14(a) and (b). Detection was at 278 nm and the lower limit of quantitation in serum was 10 ng mL\(^{-1}\). The total time for the derivatization and separation was 33 min.\(^{323}\) Alternatively, for therapeutic drug monitoring in plasma down to 10 ng mL\(^{-1}\), the determination of busulfan was based on conversion to 1,4-diiodobutane prior to HPLC separation and then UV detection of the iodide formed upon postcolumn photolysis.\(^{324}\)

4 CAPILLARY ELECTROPHORESIS

CE has developed into a versatile separation technique well suited for the determination of pharmaceutical and biomedical samples. The major advantages of CE over chromatographic separation techniques are its simplicity and efficiency. However, CE suffers from poor concentration sensitivity in detection owing to the extremely small sample volume involved. One way to improve the detection of charged analytes with weak chromophores is to use indirect detection in which an easily detected agent of the same charge is added to the running electrolyte. Replacement of the
between LC and CE can be found in the literature. A similar approach was used to determine gabapentin using 5-sulfosalicylate as the visualizing agent. CE separation and indirect laser-induced fluorescence (LIF) detection of diuretics ethacrynic acid, chlorthalidone, bendroflumethiazide, and bumetanide using fluorescein as the visualizing agent was possible in 3 min with a detection limit of 0.2 mg L$^{-1}$. A more standard approach to improve the sensitivity of CE detection is to derivatize the analytes with more favorable detection characteristics by adding either an ultraviolet/visible (UV/vis) chromophore or a fluorophore.

Derivatization chemistry previously developed for HPLC is often applicable to CE. At least one comprehensive review specifically focused on the derivatization in CE has appeared. Several other review articles dealt with more specific topics, such as postcolumn luminescence derivatization, CL derivatization, diastereomer derivatization, and dyes used to derivatize molecules for CE with LIF detection in drug analysis. The pros and cons of the various modes of derivatization and a detailed comparison of this topic between LC and CE can be found in the literature. Instead of listing the derivatization reagents suited for labeling amino, aldehyde, keto, carboxyl, hydroxyl, and sulfhydryl groups, we intend to focus on the purpose of derivatization in CE from a practical point of view, i.e. enhancing the detectability. Since UV/vis and LIF are the most common detection approaches used in CE for pharmaceutical analysis, the most recent work related to these methods is primarily discussed below. Sections on special applications and derivatization instrumental modes are also included.

4.1 Derivatization for Ultraviolet Detection

Although most organic compounds have UV/vis chromophores and CE detection is possible at 200 nm, derivatization is still important to improve selectivity of compound detection in a complex sample matrix as well as concentration detection limits. Very often, UV/vis detection of the chromophores does not give a satisfactory response owing to the very short light pathlength (50–100 µm) in CE. For example, the anticancer drug prospidin is a piperazinium derivative with chloroxypropyl groups but no UV/vis chromophore. Derivatization with diethylthiocarbamate at 37 °C for 90 min in a basic solution, with loss of HCl, generates a product that absorbs light at 254 nm. Separation of the desired product from excess derivatizing agent is possible in 10 min by CE with a detection limit of 1 ng L$^{-1}$.

Rimantadine is a synthetic analog of amantadine. Both are antiviral agents used for prophylaxis and treatment of influenza A. Because rimantadine is almost transparent in the UV/vis range, either indirect detection or derivatization has to be used to identify this compound. The indirect detection method used 5-mM 4-methylbenzylamine in 1 : 4 methanol–water as the absorbing background electrolyte for detection at 210 nm. The derivatization method used rimantadine to react with 1,2-naphthoquinone-4-sulfonic acid in an alkaline medium. CE determination of the derivative at 280 nm was performed in an uncoated capillary (44 cm × 75 -µm i.d.) using a 40-mM tetraborate buffer at pH 9.2. The detection limits were 0.1 and 2 mg L$^{-1}$ for indirect detection and derivatization methods respectively. The methods were used to determine rimantadine in pharmaceutical products and for dissolution testing of Flumadin tablets.

Most of the naturally occurring amino acids do not have proper UV/vis chromophores for CE analysis. Derivatization is a necessity for the determination of amino acids at reasonable concentrations. By using dansyl chloride to derivatize the amino acids, the enantiomeric forms of novel depsipeptide antitumor antibiotic BMY-45012, and its analogs, were determined by CE with UV/vis detection. The compounds were subjected to total hydrolysis in a vacuum hydrolysis tube with 6-M HCl at 110 °C for 24 h. The hydrolyzed residue (about 7.8 mg) was dissolved in a water–acetoniitrile solvent. For subsequent derivatization, the solution was further diluted to about 1.7 mg mL$^{-1}$ with water. Dansyl chloride dissolved in acetoniitrile (3.0 mg mL$^{-1}$) was utilized for the derivatization of standard native amino acids and those present in the hydrolyzate. A 50-µL sample solution was mixed with 50 µL of dansyl chloride solution and an aliquot of borate buffer at pH 9.08. The mixture was held at room temperature for 2 h and used directly for injection. The differing interaction of dansyl amino acids with amino-ß-cyclodextrin copper complexes in the CE running electrolyte was the basis of the chiral separation of selected dansyl amino acids. The reagent phanquinone (4,7-phenanthrolbene-5,6-dione) was applied as a prederivatizing agent for amino acids down to the sub micromolar level followed by micellar electrokinetic chromatography (MEKC) with detection at 240 nm.

Examples of other derivatization approaches for amine-containing drugs follow. Ofloxacin acyl chloride was used to modify a wide variety of drugs such as amantadine, tranexamic acid, and two amino acids
CH2
CH3
O

lary electrochromatography with a C18 column was
compared at 300 nm. The same derivatizing agent
has been applied for the determination of gabapentin
and vigabatrin at the 5-µM level. The OPA-3-
mercaptopropionic acid derivative of tobramycin could be
detected at 230 nm down to 0.1 mg L−1. Chiral separa-
tion using β-cyclodextrin of aspartic acid enantiomers
derivatized on-line by flow injection with OPA and
mercaptoethanol was possible using MEKC. Resolution of five β-blocker drugs, propranolol, oxprenolol,
pindolol, metoprolol, and atenolol, after prederivatiza-
tion with (+)-1-(9-fluorenyl)ethylchloroformate by capil-
libary electrochromatography with a C18 column was
directed toward determination of their enantiomeric
composition.

Relative binding of glycopeptides teicoplanin
and ristocetin with alanine terminus peptides before and after
reaction with acetic or succinic anhydride was an example
of affinity CE. All binding reactions were done on-
line in the capillary with the glycopeptides reacting first
with the anhydride and then with varying amounts of the
alanine terminus peptides. It was ascertained how the
modification of drugs can alter their affinities for target
molecules.

The aminocyclitol antibiotic amikacin can
be derivatized with 1-methoxycarbonylindolizine-3,5-
dicarbalddehyde at room temperature for 15 min before
determination in plasma by MEKC with UV detection at
280 nm and standard fluorescence detection (excitation
at 414 nm, emission at 482 nm). However, there was
only a twofold gain in sensitivity on switching from UV to
fluorescence detection of the amikacin derivative. If laser
excitation can be used (as discussed in the next section),
the gain in sensitivity should be significantly higher.

4.2 Derivatization for Fluorescence Detection

The principles of fluorescence and the prerequisites for a
good fluorophore, including the potential of using diode
lasers in combination with a labeling procedure, have
been reviewed previously for CE. LIF detection is
now commercially available for CE, and more industrial
scientists are using LIF detection to detect trace amounts
of analytes in complex matrices. LIF detection has several
advantages. First, it offers excellent sensitivity: under
optimized conditions, a level of 10−16 M is feasible. This
is critical to pharmaceutical applications because
sensitivity is often the most important parameter to
consider when analyzing biological samples. Second, LIF
offers a certain selectivity because, unlike UV absorbance,
LIF selectively detects compounds that are fluorescent at
certain wavelengths, and most organic compounds do not
fluoresce. On the other hand, the fact that most organic
compounds do not fluoresce is also a major limitation of
LIF detection. Since the available excitation wavelengths
of various lasers are limited, usually in the visible range,
derivatization is often required when using CE with LIF detection. The following examples demonstrate the
applicability of derivatization in CE with LIF detection
for pharmaceutical analysis.

Sulfur compounds can be converted to fluorescent
derivatives through several different reactions. Captopril,
an antihypertensive agent, was derivatized through the
thiol group with a dicarbocyanine label to give a
fluorescent derivative with a wavelength maximum at
675 nm. This wavelength was compatible with a semi-
conductor laser at 670 nm, which was used for LIF detec-
tion in conjunction with CE. Using a methanol-borate
running electrolyte, CE also separated other labeled thiols
such as cysteine and reduced glutathione from derivatized
captopril (Figure 15). The detection limit of 2.5 × 10−8 M
for captopril is limited by dilution due to the derivatization
reaction. Thiouracil and phenylmercaptoacetic acid were
derivatized with 5-iodofluorescein before CE separation and LIF
detection in the attomole range. Determination of S-
adenosyl-L-homocysteine and S-adenosyl-L-methionine

Figure 15 Electropherogram of a number of thiols labeled with CY5.3a.lA: (1) unreacted label; (2) captopril;

acid; (6) 2-mercaptoacetic acid; and (7) reduced glutathione.
(Reproduced with permission from Ref. 334.)
after chloroacetaldehyde derivatization was possible by capillary electrophoresis/laser induced fluorescence (CE/LIF) in less than 1 min.\(^{(350)}\)

Drugs with active oxygen groups such as profens, including pranoprofen, fenoprofen, ketoprofen, and ibuprofen, can be derivatized using a water-soluble benzofurazan fluorescent reagent at room temperature using a triphenyl phosphine, diphenyl sulfide catalyst.\(^{(351)}\) \(\beta\)-Cyclodextrin was added to the running electrolyte to facilitate the separation in a 50 cm \(\times\) 50 \(\mu\)M i.d. capillary. With excitation at 488 nm and emission at 50 nm, CE/LIF detection limits of 0.16–0.3 fmol were attained.

Amines can easily be derivatized with a variety of reagents that generally have optimum excitation wavelengths in the 450–500 nm region, providing compatibility with the commercial 488-nm LIF laser. Huperzine was derivatized using rhodamine B isothiocyanate, and a CE/LIF detection limit of 4 nM was found.\(^{(352)}\) Amino acids such as glycine, lysine, and glutamic acid were derivatized on-capillary with 3-(2-furoyl)quinoline-2-caboxaldehyde and detected by LIF at the 20–50-nM level.\(^{(353)}\) Using native fluorescence, alkaloids such as normorphine, morphine, 6-acetyl morphine, and codeine could only be detected at the 200 ng mL\(^{-1}\) level after CE separation.\(^{(353)}\) The same alkaloid mixture after N-demethylation with 1-chloroethyl chloroformate and then derivatization with FITC could be determined by CE/LIF at the 50–100 pg mL\(^{-1}\) level. The determination of FITC-derivatized amphetamine, methamphetamine, 3,4-methylenedioxymethamphetamine, and \(\beta\)-phenylethylamine in human urine by CE with or without dodecyl sulfate micelles using chip-based and fused-silica capillary instrumentation with LIF detection has been reported.\(^{(354)}\) The results obtained via direct labeling of fortified urine were compared with those generated after FITC labeling of urinary extracts that were prepared by SPE. Using 5 mL of urine with a “spiked amine” to FITC ratio of 1 : 250, the SPE extract had a sensitivity of 200 ng mL\(^{-1}\) urine. That value is relevant for toxicology drug screening and confirmation. In contrast, with direct labeling of 10 \(\mu\)L of urine that had been alkalized and diluted for derivatization, the limit of identification was 10 \(\mu\)g mL\(^{-1}\), a value that is too high for practical purposes. Compared to fused-silica capillaries, electrophoresis in microstructures is shown to provide faster separation and higher efficiencies without loss of accuracy and precision.

4.3 Special Applications

4.3.1 Chiral Confirmation

With proper derivatization, CE has been used for the chiral separation of enantiomeric forms of derivatized amino acids. Liu et al. reported the determination of enantiomeric forms of amino acids derived from the novel depsipeptide antitumor antibiotic BMY-45012, and its analogs, the proposed structures shown in Scheme 1.\(^{(337)}\) Amino acids were analyzed by complete hydrolysis and the hydrolyzate was derivatized with either dansyl chloride for UV absorbance detection or FITC for LIF detection in CE. For fluorescence detection, the fluorogenic reagent FITC was dissolved in acetone (0.01 M) as a stock solution. Amino acids were derivatized with FITC-derivatizing solution (5 \times 10^{-4} M) under basic conditions (borate buffer, pH 9.08). The reaction

\[
\begin{align*}
\text{Scheme 1. Structure of antibiotic BMY-45012 and its analogs. (Reproduced with permission from Liu et al. (337).)}
\end{align*}
\]
was allowed to proceed for 2–4 h in the dark at room temperature and then stored at −20 °C prior to use. Both a metal chelate chiral CE method and a cyclodextrin-mediated host–guest interaction approach in MEKC with LIF detection confirmed the presence of several chiral amino acids, such as D-serine and L-β-hydroxy-L-N-methylvaline, and the nonchiral amino acid sarcosine in the proposed structure. These methodologies provide a quick and sensitive approach for the determination of amino acid racemization in pharmaceutical natural products and have proved to be useful for structural elucidation refinement.

4.3.2 Oligosaccharide Determination

The derivatization of the pseudo-oligosaccharide acarbose (2) and its main metabolite 3 with 7-amino-naphthalene-1,3-disulfonic acid (ANDS) (Scheme 2) in human urine allowed the on-column LIF detection of the pseudo-oligosaccharides in human urine in the nanomolar range.\(^\text{(355)}\) Before derivatization, 0.5-mL samples of urine or spiked urine were evaporated to dryness. A 100 µL volume of 0.08-M ANDS solution in acetic acid–water (3 : 17 v/v) and a 50 µL volume of 0.9-M NaCNBH\(_3\) solution in dimethyl sulfoxide (DMSO) were added to each sample residue. The reagent solutions were freshly prepared before derivatization. The reaction tubes were vortex mixed and then incubated overnight at 40 °C. The efficient separation of these derivatives by CE using 100-mM triethylammonium phosphate buffer at pH 1.5 allowed the quantitation of acarbose and 3 in human urine after application of 300 mg of acarbose.

Assessment of the carbohydrate chains in glycoproteins is important for the quality control of such therapeutic antibodies.\(^\text{(356)}\) After release of the four major carbohydrates by glycoamidase, derivatives were formed with 3-amino benzoic acid and then separated by CE with LIF detection. Good precision in migration times and relative peak areas was found.

Both on-line and off-line capillary electrophoresis/mass spectrometry (CE/MS) trends for the determination of carbohydrates have been reviewed, showing the on-line sheath liquid interface with electrospray ionization (ESI) and ion trap MS detection is the most common instrumental mode.\(^\text{(357)}\) Applications include oligosaccharides from pathogens, carbohydrate-based drugs and metabolites, and characterization of glycans from glycoproteins. It was noted that prior derivatization of neutral carbohydrates to make them charged would likely improve both the CE separation and sensitivity of MS detection.

**Scheme 2.** Reaction of 2 and 3 for derivatization with ANDS by reductive amination. (Reproduced with permission from Rethfeld and Blaschke.(355).)
general method. The rMAb can be derivatized with a neutral fluorophore, e.g., 5-carboxytetramethylrhodamine succinimidyl ester (5-TAMRSE) for CE/LIF analysis.\(^{358}\) Samples containing 2.5 mg of rMAb were buffer exchanged into 800 µL of 0.1-M sodium hydrogencarbonate (pH 8.3) using a NAP-5 column. A 10 µL volume of 5-TAMRSE (1.4 mg mL\(^{-1}\)) dissolved in DMSO was then added to 190 µL of rMAb solution and the resultant mixture incubated for 2 h at 30 °C. After incubation, 190 µL of the antibody–dye conjugate was loaded on to a second NAP-5 column and collected in 700 µL of 0.1-M sodium hydrogencarbonate (pH 8.3). The labeled sample, after incubating with SDS, can be separated by CE using a hydrophilic polymer as a sieving matrix. Using these precolumn labeling conditions, the detection of rMAb at a low-nanomolar concentration (9 ng mL\(^{-1}\)) is obtained with no apparent decrease in resolution or changes to the distribution of rMAb analyte species in comparison with an unlabeled sample. This assay can be used for monitoring the consistency of the bulk manufacture of a protein pharmaceutical and in providing a size-based separation of product-related variants and nonproduct impurities. The CE/LIF with derivatization demonstrated comparable resolution and sensitivity to silver-stained sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS/PAGE) but offered the advantages of enhanced precision and robustness, speed, ease of use, and on-line detection.

CE was used for the study of palmitoyl derivatization of interferon-α\(_2\) (p-IFN-α).\(^{359}\) The derivative was prepared by covalent attachment of the fatty acid to lysine residues in the protein through a reaction with N-hydroxysuccinimide palmitate (NHSP) ester (Scheme 3). The first step involved the preparation of an intermediate NHSP, which in turn was reacted with IFN-α. CE was able to study the effect of reaction time and reagent/protein ratio.

![Scheme 3. Synthetic process for the fatty acylation of IFN-α. R–COOH palmitic acid. DCC-N,N′-dicyclohexylurea DCC-N,N′-dicyclohexylcarbodiimide (Reproduced with permission from Foldvari et al. (359).)](image)

4.4 Derivatization Modes

In general, derivatization in CE can be accomplished by either pre- or postcolumn derivatization. The precolumn derivatization is similar to methods used for derivatization in HPLC. Since CE has a much superior separation power, the interference from the derivatization by-products may be less of a problem than in LC. However, CE is very sensitive to the ionic strength of the sample. Additional sample preparation may be needed if the mixture in the derivatization reaction has a high ionic strength.

Postcolumn detection strategies have also been developed for CE. An overview of the advantages and limitations of postcolumn derivatization for CE can be found.\(^{330}\) The details about the instrumental developments and applications of postcolumn derivatization in CE can also be found in the literature.\(^{331}\) Again, much of the same derivatization chemistry developed for HPLC is applicable to CE. One exception is postcolumn photolysis, perhaps due to the difficulty of modifying commercial instruments. Using a Teflon-coated UV transparent capillary and a Pen-Ray Hg UV lamp, an on-column photoreactor has been developed for CE and applied for the determination of phytosiderophores (iron containing species) and the nonprotein amino acid nicotianamine.\(^{330}\) The relationship of irradiation window length and sensitivity was investigated, and both UV detection and contactless conductivity detection were used.

Various systems to merge the reagent solution with the separation medium have been developed, including coaxial capillary reactors, gap reactors, and free- solution or end-column systems. For all reactor types, the geometry of the system, and the method used to propel the reaction mixture (by pressure or by voltage) appear to be critical to preserve the separation efficiency. To minimize peak broadening, careful designing is necessary in terms of connecting a reagent capillary to form a tee. Because of the small (50–75 µm) i.d. of the capillaries used, normal mixing through a diffusion process is sufficient. The most frequently applied reactors are (i) coaxial, (ii) gap, (iii) free-solution, and (iv) sheath flow. With proper design, plate numbers of over 100 000 could be realized. The strict requirements on the reaction rate in postcolumn derivatization in CE limit the number of different reagents that have been used. For LIF detection, mainly OPA and its naphthalene analog have been used. With careful instrument design, the detection limits of postcolumn derivatization can be comparable to those of precolumn derivatization.

An example of postcolumn CL detection for CE is shown in Figure 16.\(^{361}\) The CL reagent tris(bipyridyl) ruthenium(II) is added at 10 µL min\(^{-1}\) using a syringe pump through a capillary into a reaction tee where it is
oxidized to the +3 state at a Pt working electrode. The CE electric field has been decoupled from the potential applied to the Pt electrode by a CE capillary fracture that is covered by a Nafion tube. This Ru(bpy)$_3^{3+}$ reactant can undergo CL with CE-separated compounds such as aliphatic amines through detection of the visible light produced at the end of the reaction tube in front of the photomultiplier (PMT) detector. Amino acids proline, valine, and phenylalanine were separated with theoretical plate numbers of 74–84 000 and detection limits in the sub 1-$\mu$M range.

5 CONCLUSION

It can be argued that the advances made in MS detection for GC, HPLC, and CE have diminished the importance of chemical derivatization for these techniques. However, chemical derivatization of drugs is critical for GC because these samples, which often contain multiple polar substituents, are simply not volatile or thermally stable. MS detection for HPLC and CE is still expensive and requires considerable operator expertise. Chemical derivatization with HPLC to permit fluorescence detection is certainly one of the more desirable methods for routine use to solve selectivity and detectability problems for drug samples not amenable to GC. As the cost of laser technology comes down, the same statement will eventually be true for CE also. The use of inexpensive light-emitting diodes as fluorescent visible and UV sources for CE also is showing promise.

1 Introduction

The stereoisomers of a molecule have the same constitution in both molecular formula and atomic bonding, but differ in the spatial orientation of the atoms or groups of atoms within the molecule. Enantiomers are stereoisomers with the same molecular formula, but which differ in the spatial arrangement of atoms within the molecule. They are nonsuperimposable mirror images, and quite often differ in their pharmacological activity, either qualitatively or quantitatively. Usually, only one of the isomers fully contributes to the therapeutic action, and the other is often classified as “isomeric ballast”. In the racemic mixtures that are used the usefulness of kinetics is generally questionable. Exposure of patients to the “isomeric ballast” present in about 50% of the most commonly used drugs will probably remain for many decades. However, approximately 50% of all drugs in therapeutic use have a chiral center, and hence about 25% of chiral drugs have been marketed as the racemate, because the choice between single stereoisomers (homochiral drugs) and composite chiral drugs (mixtures of stereoisomers) depends upon therapeutic advantages (such as a reduction in xenobiotic load), possible adverse side-effects, and development costs. Therefore, the preparation of enantiopure compounds has become very important in many branches of chemistry, and the evaluation of enantiopure compounds is required during the development of new chirally active substances and products.

In this paper, production methods for optically active compounds, especially new trends, such as the SMB method are described. Regulatory perspectives which exist in the USA, EU and Japan are outlined, and some regulatory guidelines and guidelines by, for example, the FDA and ICH are mentioned. Methods for the determination of stereoisomeric drugs, such as GC, HPLC, and CE, are summarized. The focus will be on the direct evaluation methods, i.e. those using CSPs. Practical details for testing the purity of a drug’s enantiomers are also demonstrated.

2 PRODUCTION OF CHIRAL DRUGS

2.1 History

The need for separating enantiomers for pharmaceutical applications is increasing, as regulatory aspects become more stringent. It is well known that isomers can have different therapeutic values and therefore enantiomer separation is an important issue, particularly in health-related fields. During the past few decades there have been three principal methods for producing enantiopure compounds. The first method involves numerous synthetic strategies to prepare enantiopure building blocks, or chiral auxiliary reagents. This approach is based on the development of optically active catalysts, which transfer their chiral information during the creation step of new centers of chirality. The second method involves the separation of enantiomers from racemic mixtures. One classical separation method for the preparation of enantiopure compounds is the recrystallization of diastereomeric salts. However, this is not suitable for industrial scale-up and automation. A third method uses conventional chromatographic techniques for the separation of enantiomers. This method is also difficult for scale-up because separation factors are low. Recently, much attention has been paid to continuous chromatography, particularly SMB technology because of its improved efficiency. Continuous chromatography in SMB eliminates the drawbacks of batch chromatography; namely, dilution of species and low utilization of...
adsorbents. As a production method for enantiopure compounds, SMB is described in more detail in section 2.2.

2.2 Simulated Moving Beds Technology

The concept of SMB technology has been known since 1961, when the first patent by Broughton from Universal Oil Products (UOP, Des Plaines, IL, USA) described the separation of structurally related hydrocarbons.\(^\text{22-24}\) The principle of SMB technology is a rotary valve, which periodically changes the position of feed, eluent, extract and raffinate lines along the bed. Negawa & Shoji\(^\text{25}\) reported the concept of the SMB system, as shown in Figure 1; that is, a situation where the stationary phase is moving, but in the real equipment the feed line, desorbent feed line, raffinate line and extract lines move intermittently.

It has been shown\(^\text{26-29}\) that this can be accomplished in units consisting of a set of fixed bed chromatography columns arranged in a similar manner to that illustrated in Figure 2 (boxes 1–12), where the periodic movement of inlet and outlet ports is in the same direction as the fluid flow. In Figure 2 the binary mixture \((A + B)\) to be separated constitutes the feed stream to the unit. The more adsorbable component, \(A\), is collected in the extract stream, whereas the less adsorbable one, \(B\), is collected in the raffinate stream. Each section of the unit plays a specific role in the operation. Section 1 (boxes 1–5) lies between the desorbent inlet port and the extract port; section 2 (box 6) lies between the extract port and the feed inlet port; section 3 (boxes 7–9) lies between the feed inlet port and the raffinate outlet port; section 4 (boxes 10–12) lies between the raffinate outlet port and the desorbent inlet port. Separation is performed in the two central sections. Component \(B\) is carried by the mobile phase, while component \(A\) is retained by the stationary phase. The eluent \((D)\), is used to desorb component \(A\) from the first section, in order to regenerate the adsorbent. Finally, component \(B\) is adsorbed in the

However, SMB chromatography, as a manufacturing process step, is a cost-effective method for producing chiral drugs.

3 REGULATION OF CHIRAL DRUGS

3.1 International Conference on Harmonization

In recent years, the regulatory authorities and industry associations set up to promote international harmonization of regulatory requirements have undertaken many important initiatives. Regulatory guidance on the nature and extent of investigations into the properties of chirally active substances is required, in order that the production and marketing of compounds with adverse effects can be avoided. One of the goals of harmonization is to identify and reduce differences in the technical requirements for drug development among regulatory agencies.

Six groups (Table 3), which represent the regulatory bodies and research-based industries in the EU, Japan and the USA, organize the ICH, and discuss harmonization of the technical requirements for registration of pharmaceutical products in these regions. Most new drugs and medicines are developed in the EU, Japan and the USA, and therefore when the technical requirements are agreed, new drugs can be developed and marketed without delay in these three regions. Moreover, the ICH steering committee includes representatives from each ICH sponsor and the IFPMA, as well as observers.

from the WHO, the Canada Health Protection Branch, and the EFTA. The ICH is a joint initiative, involving regulators and industry as equal partners in the scientific and technical discussions of the testing procedures required to ensure and assess the safety, quality and efficacy of medicines. Regulatory perspectives of the ICH are explained in detail in some regulatory guidelines and guidance.

3.2 Impurities in New Drug Substances and Products

The nature and concentration of impurities in new drug substances produced by chemical synthesis are regulated by the ICH guidelines “Impurities in New Drug Substances” (Topics Q3A) and “Impurities in New Drug Products” (Topics Q3B) which deal with chemical and safety aspects. Classification and identification of impurities are included in chemical aspects. Threshold limits for drug impurities should depend on each individual drug and be based on scientific rationale. The structures of impurities that occur at concentrations of 0.1%, or greater have to be determined. New drugs used for preclinical and/or clinical studies can have impurities. If the proposed concentration of an impurity is not specified, the safety of that impurity has to be studied according to the threshold limits given in Table 4. Although impurities in new drug substances and products are regulated, the guidelines do not apply to enantiomeric impurities in new chiral drugs, even though enantiomeric impurities may be regarded as conventional impurities.

3.3 Guidance for Chiral Active Substances

The FDA’s policy statement for the development of new stereoisomeric drugs was issued in 1992. Later, a Note for Guidance on the Investigation of Chiral Active Substances was approved in June 1997 by the CVMP. This “Note” is valid from January 1, 1998. According to the “Note”, the identity and stereoisomeric purity of the active substance, its optical rotation (OR), melting point, and characteristics when undergoing liquid chromatography using a CSP have to be studied.

However, chiral impurities of new optically active drug substances are excluded from the ICH Guidelines because of practical difficulties in quantifying them and identifying the given thresholds. Chiral impurities in chiral new drug substances and new drug products should be treated according to a decision tree, as outlined in Figure 3, and the ICH Guidelines “Test for new drug substances that are optically active” (Table 5) (Topics Q6A). At present, the concentration of the antipode, that is, the chiral impurity of chiral drugs, is not regulated in Topics Q6A, but, ideally, the antipode should be regulated as an impurity. As described in Table 4, if the toxicity of the antipode is unclear, methods have to be available which will detect 0.05% chiral impurity.

4 EVALUATION METHODS FOR CHIRAL DRUGS

Over the last two decades, chiral analytical technology and chiral purity in drug analysis have acquired increasing prominence, because various aspects of pharmaceutical activity, such as pharmacology, drug quality control, toxicology, require these analysis. For these purposes, powerful and widely applicable analytical tools are needed to determine the enantiomeric purity of chiral drugs. Chromatographic methods using GC, HPLC, and electrophoretic methods such as CE have been developed.
Figure 3  Decision tree to establish the identity, assay and chiral impurities procedures in a new drug product containing a chiral drug substance.

Table 5  Tests for new drug substances and products that are optically active

<table>
<thead>
<tr>
<th>Impurity or degradation product</th>
<th>Drug substance</th>
<th>Drug product</th>
</tr>
</thead>
<tbody>
<tr>
<td>Impurities: for chiral drug substances that are developed as a single enantiomer, control of the other enantiomer should be considered in the same manner as for other impurities. However, technical limitations may preclude the same limits of determination or qualification being applied. If it is technically difficult to effect control in the drug substance itself, assurance of control could be given by appropriate testing of a starting material or intermediate, with suitable justification.</td>
<td>Degradation products: control of the other enantiomer in a drug product is necessary if that enantiomer has been shown to be a degradation product.</td>
<td></td>
</tr>
<tr>
<td>Assay</td>
<td>An enantioselective determination of the drug substance should be part of the specification. It is considered acceptable for this to be achieved either through use of a chiral assay procedure or by the combination of an achiral assay together with appropriate methods of controlling the enantiomeric impurity.</td>
<td>Where development studies have demonstrated that the enantiomer is not a degradation product, an achiral assay may be sufficient. However, a chiral assay is preferred or, alternatively, the combination of an achiral assay plus a procedure to control the presence of the opposite enantiomer.</td>
</tr>
<tr>
<td>Identity</td>
<td>The identity test(s) should be capable of distinguishing a single enantiomer from its opposite enantiomer. Where a drug substance is a racemate, the identity method should be capable of verifying the racemic nature and distinguishing it from either enantiomer.</td>
<td>An identity test should be established that is capable of verifying the presence of the correct enantiomer or the racemate, as appropriate.</td>
</tr>
</tbody>
</table>
In principle, there are three methods of separating enantiomers: (1) by using enantiopure derivatizing reagents to convert enantiomers to diastereomers, which can then be separated on an achiral column; (2) by using chiral mobile phases (except GC); and (3) by using CSPs.

### 4.1 Gas Chromatography

The first CSP for separating enantiomers by GC was synthesized in 1977 by coupling polysiloxane and L-valine-tert-butylamide, which is now available commercially as Chirasil-Val (Chrompack, Middelburg, The Netherlands). Separation of 11 mixtures of alcohol enantiomers, as isopropyl urethane derivatives, by Chirasil-Val is shown in Figure 4. The separation was completed within 40 min. Separation of the enantiomers of sulfur compounds was also successful within 30 min. Saeed et al. and König et al. synthesized chiral polysiloxane attached to either L-valine-tert-butylamide or L-valine-(S or R)-phenylethylamide as a chiral moiety. Fused-silica capillary columns coated with various CDs linked to the polymer have also been developed. Chirasil-Dex, where the β-CD was linked to the polymer through only one 6-O-octamethylene spacing group, was introduced by Jung & Schurig, and is now available commercially. A summary of recently developed, commercially available CSPs is given in Table 6. The advantages of GC for the separation of enantiomers are the high efficiency, sensitivity, and speed of chiral separation. The disadvantages are that the volatility, thermal stability and resolvability of the analyte limit the usefulness of the technique. However, GC is useful for separating enantiomers of nonaromatic ring compounds, which cannot be detected by the systems used with HPLC.

### 4.2 High-performance Liquid Chromatography

#### 4.2.1 Chiral Derivatization

Approximately 30% of chiral compounds have been analyzed by indirect methods, because they could not be separated by using CSPs. The indirect method is based on the reaction of a racemic mixture with a chiral reagent to form a pair of diastereomers, which possess different physicochemical properties and hence can be separated by an achiral column. The acid chloride of (S)-(−)-N-trifluoroacetyltartaric anhydride is a widely used derivatizing agent and has been used for resolving racemic amines and alcohols by normal-phase chromatography. (S)-(−)-N-1-(2-naphthylsulfonyl)-2-pyridylidene carbonyl chloride (NSP-Cl), a derivatizing reagent for primary or secondary amines and alcohols, has been successfully used for determining the enantiomeric purity of diltiazem hydrochloride (a Ca2+ channel blocker), and enprostil (an anti-ulcer drug). The derivatized enantiomers were separated by normal-phase chromatography. 2,3,4,6-Tetra-O-acetyl-β-D-glucopyranosyl isothiocyanate (GITC), which was developed by Kinoshita et al. and Nimura et al. as a derivatizing reagent for an amino group, has also been successfully used in reversed-phase HPLC for determining the enantiomeric purity of denopamine, etilefrine, phenylephrine and trimethoxiquinol hydrochloride. 1-(9-Fluorenyl)ethyl chlorothioformate (FLEC) has been widely used for the diastereomeric derivatization of primary or secondary amines and alcohols. For carboxylic acids, or their derivatives, of biological interest, separation of enantiomers can be achieved by using reversed-phase HPLC with an ODS column, after derivatization with alanine-β-naphthylamide. This method was used by Kagawa et al. to determine the enantiomeric purity of acetyl-L-carnitine, which may be important as it can stimulate actions of learning behavior and can be used as a drug. Typical chromatograms are shown in Figure 5.

#### 4.2.2 Chiral Stationary Phases

Direct methods using CSPs have been used extensively because CSPs based on amino acid derivatives, cellulose, CDs, ovomucoid, bovine serum albumin, crown ethers, and antibiotics (Figure 6) are now available commercially (Table 7).

Recently, in the development of new chiral drugs, most determinations of chiral purity in drug analysis have been performed by using CSPs. For example, in our laboratory, direct separation of the enantiomers of diltiazem hydrochloride, which was previously achieved by derivatization with NSP-Cl, was achieved by using
ovomucoid CSP, where protein is embedded on a silica-gel matrix. With this method, good linearity between the peak area and the amount of sample used permitted determination of the enantiomeric purity of the antipode at levels down to about 0.1%. In 1994, direct separation of the enantiomers of imidapril hydrochloride, which previously required chiral derivatization, was achieved by using the CSP Chiralpak WH, a ligand-exchange type column where Cu$^{2+}$ is used as a mobile phase additive. With this method, good linearity between the peak area and the amount of sample used, combined with a signal-to-noise ratio of 3, gave a detection limit of about 0.2% for the antipode. In our laboratory approximately 70% of chiral separations of drugs have been achieved by using CSPs.

Dolezalova & Tkaczykova reported the enantiomeric purity of levodopa and carbidopa (L-DOPA and L-CDOPA, respectively, both of which are used for the treatment of Parkinson’s disease), and methyl-dopa (L-MDOPA, used as an antihypertensive) by using Chirobiotic T, in which teicoplanin is used as a chiral moiety. The detection limits of the antipode on L-DOPA, L-MDOPA and L-CDOPA were 0.03%, 0.3% and 0.4%, respectively. Torrens et al. reported the enantiomeric purity of levodopa and carbidopa (L-DOPA and L-CDOPA, respectively, both of which are used for the treatment of Parkinson’s disease), and methyl-dopa (L-MDOPA, used as an antihypertensive) by using Chirobiotic T, in which teicoplanin is used as a chiral moiety. The detection limits of the antipode on L-DOPA, L-MDOPA and L-CDOPA were 0.03%, 0.3% and 0.4%, respectively. Torrens et al. reported the enantiomeric purity of levodopa and carbidopa (L-DOPA and L-CDOPA, respectively, both of which are used for the treatment of Parkinson’s disease), and methyl-dopa (L-MDOPA, used as an antihypertensive) by using Chirobiotic T, in which teicoplanin is used as a chiral moiety. The detection limits of the antipode on L-DOPA, L-MDOPA and L-CDOPA were 0.03%, 0.3% and 0.4%, respectively. Torrens et al.

purity of cizolirtine, a potent analgesic that is currently in phase II clinical trials, by three independent methods, namely, $^1$H-NMR (nuclear magnetic resonance), CE (using $\beta$-CDs as chiral resolving agents) and HPLC (using a Chiral AGP column). Typical chromatograms are shown in Figure 7. The detection limits of the antipode obtained by the three methods were: 1% with $^1$H-NMR, and 0.5% with either HPLC or CE.

Despite the numerous CSPs now available commercially, much research is still carried out to develop novel CSPs that have wider or more specialized enantioselectivity. Pirkle & Terfloth$^{91}$ developed a new CSP derived from S-naproxen as the chiral moiety. Haginaka et al.$^{92}$ investigated the separation of enantiomers on a CSP based on ovoglycoprotein and the effect of aggregation of ovoglycoprotein. 18-Crown-6-tetracarboxylic acid, which has a high enantioselectivity for primary amino compounds, has been immobilized to silica gel as the chiral selector.$^{93–95}$

In addition to the development of CSPs, some applications for mobile phase additives have also been published. Separation of the enantiomers of hydrophobic amino compounds by using Crownpak CR$,^+$, dynamically coated chiral crown ether as chiral moiety, has been studied.$^{96}$ Here, the enantiomeric hydrophobic amino compounds were easily eluted and successfully separated by the addition of $\beta$-CD (an inclusion reagent) and/or various salts. Typical chromatograms are shown in Figure 8.

Novel detectors for the stereospecific analysis of chiral drugs in plasma have been developed and investigated. In 1999, Kanazawa et al.$^{97}$ reported the separation of enantiomers of lorazepam, ibuprofen and flubiprofen on Chiralcel OD, using UV, circular dichroism and OR detection systems. Typical chromatograms of ibuprofen are shown in Figure 9. Chiroptical detection systems, such as circular dichroism and OR, are useful for pharmacokinetic studies of chiral drugs in biological samples, because the front peak and other peaks having no chirality are not detected by these methods.

For future CSPs, molecular imprinting (MI) technology is likely to be introduced. The technique of MI is shown schematically in Figure 10.$^{98,99}$ The selected analyte or

*template molecules is first allowed to establish binding interactions with polymerizable chemical functionalities, that is, hydrogen bonds, ion pairing, π–π interaction or hydrophobic-effect-driven reactions, and the resulting complexes or adducts are subsequently copolymerized with crosslinkers into a rigid polymer. After the template molecules are extracted, specific recognition sites are left in the polymer in which the spatial arrangement of the functional groups in the polymer network, together with the shape, are complementary to the imprinted molecule. Therefore, an MI polymer appears to have the potential for chiral recognition, and an analytical method using an MI polymer will be a powerful tool for chiral separation of drugs.*

**4.3 Capillary Electrophoresis**

CE is another powerful method for separating enantiomers.\(^{100-103}\) Relatively fast separation, with high resolution, can be achieved with one capillary tube, without a special chiral column or an organic solvent. Furthermore, CE has many attractive features, such as the speed of method development and analysis, robustness, simplicity and cost. The separation solution can easily be altered to find the optimum separation media, and an expensive chiral selector can be used because only small amounts of media are required. Among various different CE modes, both capillary zone electrophoresis (CZE) and electrokinetic chromatography (EKC), in which only a chiral selector is added to the usual running buffer solution, are most widely used for enantiomer separations.\(^{100,101}\) EKC, where an ionic pseudo-stationary phase is employed, is one branch of the CE techniques and has the capability to separate electrically neutral analytes. Various ionic additives or aggregates, such as micelles, microemulsions, and vesicles have been used as a pseudo-stationary phase in EKC. Among them, EKC using micelles, i.e. micellar EKC (MEKC) has become most popular.\(^{104,105}\) Normally, an ionic surfactant (e.g. sodium dodecyl sulfate, SDS; or bile salts) solution is used as a running buffer solution in MEKC.

Typically, for the enantiomer separation of ionic analytes, neutral chiral selectors are employed in the CZE mode. CDs and their various derivatives have been
found to be most effective in CZE for a wide range of drugs. On the other hand, charged pseudostationary phases having chirality are added to the running buffer solution in EKC. Therefore, EKC enantiomer separation can be applied to both ionic and nonionic analytes. CDs are also effective chiral selectors in the MEKC mode. This mode is called CD modified MEKC (CD/MEKC). CDs, polysaccharides, proteins,
crown ethers, and chiral surfactants, which are also effective chiral moieties in HPLC have been found to be useful in CE for the separation of enantiomers. Typical chiral selectors that have been successfully employed for the CE enantiomer separations are shown in Figure 11.

4.3.1 Use of Cyclodextrins and Crown Ethers

Among the various chiral selectors used in CE for separation of enantiomers, CDs have attained the greatest popularity, because they are capable of recognizing a wide range of enantiomers. When neutral CDs are used, the separation mode is called CD/CZE, and enantiomers of basic and acidic drugs can be separated. One example is shown in Figure 12, where ropivacaine and its enantiomer (R-form), and other related derivatives (enantiomers) have been successfully separated by CD/CZE. The running buffer was 0.1 M phosphoric acid, pH 3.0 (adjusted by triethanolamine), containing 10 mM 2,6-dimethyl (DM)-β-CD. Detection was at 206 nm. The method also detected the required 0.1% of enantiomeric impurity, and proved to be robust. Some of these CE enantiomer purity testings have been accepted as a part of regulatory submissions or submitted to the FDA or the pharmacopoeias. Enantiomers of various ionic drugs have been successfully separated by this CD/CZE mode, using one of these CD derivatives. Recently, CE enantiomer separations by the combination of neutral CDs and other additives, such as surfactants (CD/MEKC mode), charged CDs (dual CD system), and crown ethers, have been demonstrated. By combining CDs with another additive that can interact with the analytes, enantioselectivity has been much improved. For example, the enantiomers of 1-aminoindan, could not be separated by CZE with either 18-crown-6 or DM-β-CD, but were successfully separated by CZE using 5 mM 18-crown-6 and 5 mM DM-β-CD. Enantiomers of some other aminocompounds, such as 1,2,3,4-tetrahydro-1-naphthylamine, and 1-methyl-3-phenylpropylamine, have also been successfully separated by a dual system using CDs and crown ethers.

Charged CDs have also been successfully used alone (CD/EKC) or with other additives, such as neutral CDs (dual CD system). Various anionic CD derivatives, such as sulfobutyl ether-, phosphated-, sulfated-, or carboxymethylated-, are now available commercially. Positively charged CD derivatives, such as 2-hydroxypropyltrimethylammonium β-CD, hepta-methylamino- and 6A-methylamino-β-CD, have been synthesized and used in CE for separation of enantiomers. Enantiomers of acidic pharmaceuticals that have a carboxylic group, such as nonsteroidal anti-inflammatory agents (e.g. ibuprofen, naproxen, ketoprofen) have been successfully separated by using these cationic CD derivatives, that is, by the CD/EKC mode.

Recent developments in the use of CDs as chiral selectors for CE include the use of charged CDs for separation of enantiomers. Charged CDs have been used in the CD/EKC mode and in dual CD systems. The use of charged CDs has been shown to improve enantioselectivity and provide better separation of enantiomers.

Figure 11 Typical chiral selectors used for CE enantiomer separations.
It is often difficult to control the position and the number of the substituents in these synthesized CD derivatives. The substitution distribution significantly influences the enantioselectivity. One example is the separation of enantiomers of denopamine and trimetoquinol by CZE with DM-β-CD. Resolution values obtained from six different commercial DM-β-CD were different and showed that the degree of methyl substitution probably differed. This was confirmed by HPLC purity testing and matrix-assisted laser desorption ionization/time-of-flight mass spectrometry (MALDI/TOFMS) analysis. To overcome these problems, single-isomer sulfated CDs have been developed recently. Various enantiomers were successfully separated, as in the randomly derivatized charged CDs. Reproducibility in the enantioselectivity will be controlled by using these single-isomer derivatives.

The chiral crown ether, 18-crown-6-tetracarboxylic acid, has been shown to be effective for the separation of chiral amino drugs. Compared with the results obtained by HPLC with a commercially available chiral crown ether column (Crownpak CR(+)), CE with 18-crown-6-tetracarboxylic acid was effective for the separation of enantiomers where the amine functional group and the stereogenic center is long. In a nonaqueous CE mode with formamide, enantiomer separation of 1-phenylethylamine, which has not been separated by any other mode of CE, was achieved by adding the tetra-n-butylammonium salt to the running buffer containing 18-crown-6-tetracarboxylic acid. It is expected that various chiral crown ethers that can be applied in the CE system will be developed, because, at present, only 18-crown-6-tetracarboxylic acid is available commercially.

4.3.2 Use of Polysaccharides, Antibiotics and Proteins

Polysaccharides, antibiotics, and proteins have been successfully used in CE for separation of enantiomers. Polysaccharides, such as chondroitin sulfates, dextran...
sulfates, heparin, dextrans, dextrins, pentosan polysulfate, and dermatan sulfate, have been used as chiral selectors.\(^{(119-123)}\) Dextran sulfate and pentosan polysulfate are semisynthetic sulfated polyanions. When charged polysaccharides are used as chiral selectors, the ionic character is important. In these polysaccharides, pentosan polysulfate has more ionizable groups per monomer unit (about two) than do chondroitin sulfates, dermatan sulfate (about one) and heparin, (one to two), and fewer than dextran sulfate (two to three). Enantiomers of tryptophan analogs\(^{(121)}\) and basic pharmaceuticals\(^{(119-122)}\) have been successfully separated by CE with ionic polysaccharides. One example is shown in Figure 13. Enantiomers of diltaizem hydrochloride (a Ca\(^{2+}\) channel blocker, in which the 2S,3S-form is active) and sulconazole (an antifungal, and a racemic drug) have been successfully separated by CZE using simply dextrin addition to a pH 2.5 phosphate buffer.\(^{(123)}\)

Glycopeptide macrocyclic antibiotics such as vancomycin, teicoplanin, ristocetin A, and avoparcin, and some other antibiotics, such as rifamycins (B and SV), and aminoglycosides (kanamycin, fradiomycin, and streptomycin) appear to be among the most useful chiral selectors available for CE.\(^{(124,125)}\) Recently, two different vancomycin analogs, namely A82846B and LY307599, and the teicoplanin family antibiotic MDL 63246 have been used to analyze negatively charged enantiomers.\(^{(124)}\) High enantioselectivity has been shown by using these antibiotics, for example in HPLC with CSP moiety. However, some attention should be paid to the use of these

**Figure 12** Enantiomer purity testing of ropivacaine (4S-form) by CZE using DM-β-CD. (a) Separation of related enantiomers including the ropivacaine minor enantiomer (4R-form); and (b) detection limit (0.1%) of the minor enantiomer. Applied voltage, 30 kV. Separation tube, 50 μm i.d. × 80.5 cm (effective length 72.0 cm). Detection, 206 nm. Temperature, 30°C. (Reproduced from van der Griend and Groningsson.\(^{(100)}\) with permission from Elsevier Science.)
antibiotics in CE because their strong UV absorption affects the sensitivity of the technique.

Proteins such as bovine serum albumin, human serum albumin, α1-acid glycoprotein, avidin, ovomucoid, casein, cellubiohydrolyase, cellulase (fungal), transferrin (human serum), and pepsin, have also been found useful in CE for enantiomer separation.\(^{126-128}\) Proteins have strong UV absorption in the typical UV detection wavelength range of 200–280 nm, therefore partial filling techniques have been used to avoid severe disturbances in UV detection.\(^{127,128}\) This technique, where only a part of the capillary is filled with the selector, is also very useful in CE for enantiomer separations with antibiotics.

### 4.3.3 Micellar Electrokinetic Chromatography and Capillary Electrophoresis for Separation of Enantiomers

Chiral surfactants have been used for enantiomer separation in MEKC,\(^ {129,130}\) either when used on their own or in conjunction with other buffer additives such as CDs. Natural surfactants such as bile salts, digitonin, and saponins, and semi-synthetic surfactants derived from naturally occurring sugars\(^ {131,132}\) and amino acids\(^ {133,134}\) have been used. Recently polymerized surfactants have been used as chiral selectors in MEKC.\(^ {135,136}\) Compared with conventional micelles, which consist of a monomer surfactant, there are various advantages in polymer type micelles. The elimination of the dynamic equilibrium between the monomer and micelle may enhance chiral recognition. The critical micelle concentration of these polymer type micelles is essentially zero. This means that the polymer can be used over a wider range of concentrations. Organic modifiers can also be used without disrupting the formation of the micelle.

Separation by capillary electrochromatography (CEC) has recently attracted considerable interest due to the improved efficiency, as in conventional micro-HPLC. In addition, a wide variety of different packing materials developed for CEC are already available commercially.\(^ {137}\) The application of CEC has mainly focused on separations of electrically neutral drugs, because the separation mechanism of CEC is chromatography itself. Separation of enantiomers is another area where CEC holds tremendous potential. Capillaries packed with CDs as the immobilized stationary phases\(^ {138,139}\) have been used. A wide variety of CSPs such as polysaccharide derived,\(^ {140}\) naproxen derived, and Whelk-O\(^ {141}\) have been prepared. MI has also been used in CEC to obtain capillaries with predetermined chiral selectivities.\(^ {142,143}\)

### 4.3.4 Regulatory Aspects

The acceptability of CE methods in drug analysis (including New Drug Applications (NDAs)) by regulatory authorities is one of the topics for pharmaceutical companies. Validations according to the ICH\(^ {144,145}\) or pharmacopoeia guidelines\(^ {146}\) are required in order that CE can be used as routine quality control methods by the pharmaceutical companies or when presenting NDAs.

In modern, automated CE instruments, where a capillary is thermostated by an oven or liquid coolant, and sample injection and capillary washing are performed by computer, usually around 1% relative standard deviation (RSD) are obtained for the peak area ratios in the repeated injection (five or six injections). Accordingly, in the testing method of a drug, typically 2% or 3% values (corresponding to 2 RSD or 3 RSD values) are adopted as a criterion for the system suitability test (see below). Appropriate CE data, meeting the requirements of ICH guidelines, have been included in a regulatory submission.\(^ {147,148}\) An assay that indicates the stability and uniformity of content of the cholesterol-lowering agent BMS-188494 by the MEKC method has been accepted as part of a regulatory submission to the
A running buffer containing 0.1 M borate and 0.025 M SDS was used, and detection was carried out at 200 nm.

Pharmacopeia have also recognized the advancing application of CE within pharmaceutical companies. The savings in solvent purchase and disposal have been highlighted, particularly from an environmental viewpoint. Furthermore, a draft general chapter on CE has been published for the US Pharmacopeia (USP). The first USP monographs describing CE were published in 1997. These are chiral separation methods for epinephrine borate ophthalmic solution, and a separate procedure for the analysis of ethambutol content in tablets. In epinephrine borate injection, DM-β-CD has been used for separating the enantiomers (−)-epinephrine and (+)-epinephrine. Relative migration times, tailing factors of peaks, resolution and RSD values for replicate injections are specified in system suitability testing as follows. Both resolution values between the enantiomers, and the (−)-form and internal standards are not less than 1.5. Tailing factors for all peaks are not more than 2.5. An RSD of the ratio of (−)-epinephrine (active component) and (−)-pseudoepinephrine (internal standards) is not more than 3.0%. The relative migration times, resolution and RSD have been also specified in the assay of ethambutol. Resolution between the active component and internal standards is not less than 2. The RSD for the peak area ratio is not more than 2.0%. As a result of the ICH, groups representing the USP, European Pharmacopoeia and Japanese Pharmacopoeia have discussed the harmonization of general methods and monographs for drug substances. This has led to the publication of harmonized information concerning CE, as official inquiry stage draft. (151)

5 CONCLUSION

Recently, regulatory authorities have discussed the level of antipode and stereoselective analytical methods with industry associations. Some drafts such as ICH guidelines (Q3A, Q3B and Q6A) have been proposed. For chiral analysis and chiral purity determination in drug analysis, various CSPs have been developed and most are now available commercially. Further CE technology has also been used for chiral analysis because of its advantages. By using these technologies, a concentration of 0.1% of the minor enantiomer, can be easily determined, as required by regulatory authorities. In the near future, it is expected that more than 90% of enantiomers will be separated by using novel CSPs or chiral separation technologies. On the other hand, high sensitivity, nonseparated chiral purity determination methods using mass spectrometry (MS) or NMR technology may be introduced for drug analysis.

COMBINATORIAL CHEMISTRY LIBRARIES, ANALYSIS OF

Combinatorial Chemistry Libraries, Analysis of

Christopher E. Kibbey
Parke-Davis Pharmaceutical Research, Division of Warner–Lambert Company, Ann Arbor, USA

1 Introduction

Many of the analytical techniques applied to the analysis of traditional pharmaceutical compounds are used to characterize combinatorial chemistry libraries. In both cases, the medicinal chemist is primarily concerned with verifying the identity and purity of the compounds synthesized. The identity of a compound usually is confirmed spectroscopically by Fourier transform infrared (FTIR) spectroscopy, mass spectrometry (MS), and/or nuclear magnetic resonance (NMR) spectroscopy, while purity is determined using a chromatographic technique, such as high-performance liquid chromatography (HPLC). Combinatorial chemistry libraries may contain 100–100 000 compounds present as single species or as mixtures. The need to efficiently characterize such large numbers of compounds has been the primary motivation behind the development of many of the chromatographic–spectroscopic techniques applied to the analysis of combinatorial chemistry libraries. Many of these techniques have utility outside of the realm of normal library characterization. For example, the combination of affinity chromatography and MS has proven useful for screening combinatorial chemistry libraries against specific biological targets. The major impediments to the analysis of combinatorial chemistry libraries have been the challenges of designing analytical methods compatible with the wide chemical diversity of compounds encountered in these libraries, and the unique sample preparation and handling requirements imposed by combinatorial synthesis.

1 INTRODUCTION

The drive to improve the efficiency of the drug discovery process has created the need for rapid compound synthesis and efficient methods for screening compounds for biological activity. The fields of combinatorial chemistry and high-throughput screening matured during the early 1990s to meet the challenges of modern pharmaceutical research. Solid-phase synthesis (SPS) and parallel solution-phase synthesis techniques have the potential to deliver hundreds of thousands of compounds in a relatively short period of time. However, the emergence of these combinatorial chemistry techniques has created the additional demand for new analytical techniques to follow the course of chemical reactions and characterize final products. This article begins with a brief overview of the basic concepts of combinatorial
chemistry, and follows with a description of many of the proven analytical techniques employed in combinatorial chemistry laboratories.

2 COMBINATORIAL CHEMISTRY

The field of combinatorial chemistry originally focused on the automated synthesis of peptide and small molecule libraries for drug discovery. Invariably, these compounds were assembled on chemical scaffolds immobilized on a solid support. However, with the rapid development of new technologies to synthesize compounds en masse, and the application of these techniques to fields outside of pharmaceutical research, the field of combinatorial chemistry has been in need of a more comprehensive definition. While a formal definition has yet to emerge, combinatorial chemistry may be described as a process of synthesizing sets of structurally related compounds by reacting all possible combinations of a limited number of chemical reagents according to a general reaction scheme in a manner compatible with the subsequent screening of the products for specific properties. The following sections provide an overview of the techniques that have emerged in the field of combinatorial chemistry.

2.1 Solid-phase Synthesis

The beginnings of modern SPS date back to Merrifield’s work on solid-phase peptide synthesis (SPPS) in the early 1960s.1 By the early 1970s a number of researchers, including Rapoport and Crowley,2 Patchornik and Kraus,3 and Leznoff and Wong,4 had reported the preparation of nonpeptide heterocyclic compounds by solid-phase organic synthesis (SPOS). Automated peptide synthesizers became commercially available in the early 1980s. Further interest in SPS was sparked during this time by breakthroughs in phosphoramidite chemistry5 which brought forth DNA SPS. A quantum leap in SPS during the mid-1980s grew out of the efforts of Geysen et al.,6 Furka et al.,7 Houghten,8 Lam et al.,9 and Fodor et al.10 to increase the efficiency of SPPS through parallel synthesis. By the mid-1990s, many of the major pharmaceutical companies in the United States had established research groups to exploit the benefits of SPOS.

The primary advantages of SPOS over traditional synthesis are twofold. First, reactions on solid supports can be driven to completion through the use of excess reagents. Second, products can be isolated with reasonable purity by simply washing the excess reagents away with organic solvent. Using modern SPS techniques, it is possible to synthesize hundreds of thousands to millions of compounds simultaneously. Despite its universal acceptance in the pharmaceutical industry, SPOS is still in its infancy. The repertoire of synthetic organic reactions that have been carried out on solid-phase supports11,12 represents only a small fraction of the chemistries available to the field of organic chemistry. A factor that has limited the use of SPOS in pharmaceutical research is the three to six month lead-time required to optimize new chemistries on solid supports.

The majority of SPS work is carried out on spherical polymeric supports (beads) composed of either polystyrene cross-linked 1–2% divinylbenzene, or polyethylene glycol–polystyrene block copolymer. A notable exception is the functionalized polyethylene–poly(N,N-dimethylacrylamide/methacrylic acid) graft copolymer “pins” developed by Geysen et al. for peptide epitope mapping.6,13 The surface of the resin beads used in SPOS contains active functional groups (linkers), which serve as sites for attachment during synthesis. The structures of a number of the more common linkers used in SPOS are shown in Figure 1.

2.2 Mixture Synthesis

The most straightforward approach to synthesizing multiple compounds in parallel on a solid support is to treat an appropriate resin-bound intermediate with a solution containing equimolar quantities of various reagents. Cleavage of the reaction products from the solid support will yield, in theory, an equimolar mixture of the desired products. This is precisely the approach taken by researchers, such as Geysen et al.,14 involved in the synthesis of peptide libraries in the mid-1980s. The potential of this technique, however, is less promising when one considers that the reactivity of a reagent is highly compound specific. Rather than providing an equimolar distribution of products, the method usually results in a wide distribution of product yields. When the technique is applied to peptide synthesis, small variations in the reactivity of amino acids can be overcome through variation of the concentration of each reactant in the reaction mixture.15 If the reactions are very efficient, it is possible to obtain equimolar product mixtures by using only one equivalent of each reactant in the coupling step.16 Mixture synthesis is generally impractical for the synthesis of nonpeptide libraries.

2.3 Split Synthesis

Furka et al.17,18 developed the “split synthesis” strategy for parallel synthesis to overcome the difficulties involved in using reagents with different chemical reactivities. In the split synthesis technique, a common pool of resin-bound intermediates is divided into equal pools, each pool is coupled with a separate reagent, and the resin
pools are then recombined into one. Multiple iterations of dividing, coupling, and pooling resin beads result in a mixture of resin-bound products, where each single bead consists of only one set of product molecules. An example of the split synthesis of a library of nine hypothetical compounds is illustrated in Figure 2. The advantage of the split synthesis technique is that the number of products grows geometrically with each iteration of the divide–couple–pool cycle. For oligomers the number of possible products equals $X^n$, where $X$ is the number of starting monomers and $n$ is the number of reaction cycles.

2.4 Spatially Addressed Synthesis

Spatially addressed synthesis is a special case of parallel synthesis developed by Fodor et al. at Affymax Research. The technique uses photolithography to synthesize arrays of up to 100,000 discrete compounds on silica wafers approximately 1 cm$^2$ in area. Active functional groups are attached to the surface of the silica substrate and their termini blocked with photolabile protecting groups (see Figure 3). Specially designed masks are laid over the surface of the silica wafer, and laser light is used to cleave exposed protecting groups from the surface. The wafer is then immersed in a reaction solution consisting of a reagent derivatized with a photolabile protecting group. The deprotected active sites on the silica wafer react with the protected reagents in the solution to form a protected oligomer. Peptide libraries may be synthesized through repeated application of the laser deprotection and coupling steps. The structure of any compound in the spatially addressable array may be inferred from its location on the silica surface and knowledge of the masking scheme and order of reagent additions.

2.5 Encoding Strategies

Combinatorial libraries prepared by split synthesis always result in mixtures, rather than discrete products. When a “hit” is obtained in a biological assay, it becomes necessary to identify the active member in the test mixture. Deconvolution of an active well usually involves iterative resynthesis and testing. An example of deconvolution of a 1000 component library of oligomers is shown in Figure 4. In this example, the combinatorial library is prepared by split synthesis involving ten sets
Figure 2 Split synthesis of a nine-member combinatorial library.

Figure 4 Deconvolution of a 1000-component library by iterative screening and resynthesis.

Figure 3 Light-directed, spatially addressable chemical synthesis. (Reprinted with permission from L.A. Thompson, J.A. Ellman, Chem. Rev., 96, 555–600 (1996). Copyright 1996 American Chemical Society.)

of monomers and three sequential reaction steps (i.e. $10 \times 10 \times 10 = 1000$) to give ten sets of oligomers. If the third well is biologically active, then the identity of the third monomer of the active compound is known from the last step of the synthesis. The identity of the second monomer of the active compound may be determined through resynthesis of a 100 component library by randomizing the first monomer, terminating the split at the end of the second reaction step, and fixing the position of the third monomer. In turn, the identity of the first
monomer of the active oligomer may be determined by fixing the positions of the second and third monomers. The added burden of performing multiple resynthesis and the complications involved in deconvoluting libraries containing multiple active compounds have led researchers to devise other strategies for identifying the active components in mixture libraries. A number of encoding strategies have been developed by various researchers, and those based on DNA strands, peptide strands, molecular tags and radiofrequency (RF) transponders are described. Simply stated, an encoding strategy involves “tagging” resin beads at each step of a split synthesis, such that the identity of a compound on any bead can be determined by decoding the tag sequence. A generic example of library encoding is shown in Figure 5. The advantages of the encoding strategy are threefold. First, tagging schemes permit identification of all of the biologically active compounds in a mixture library, whereas deconvolution usually gives the most active library member. Second, rigorous analytical characterization of the library products is avoided, because compound identity is inferred from the tag sequence. A compound’s identity can be verified faster by decoding a tag sequence, than by structural characterization. Third, encoding requires fewer synthetic steps than the iterative synthesis involved in library deconvolution. It is important to bear in mind, however, that the encoding process is independent of the reaction steps in split synthesis. Hence, failure of a reaction step will lead to an incorrect product assignment.

2.5.1 Oligonucleotide Tags

The first tagging strategy for combinatorial chemistry was reported by Brenner et al.\(^{19,20}\) and involved encoding peptide libraries using oligonucleotide sequences. A pair of alternating combinatorial syntheses was used to attach the DNA strands and peptide monomers to separate sites on the bead surface. This encoding technique requires at least 15 nucleotides in the coding region for effective hybridization. Thus, a combinatorial synthesis involving five coupling steps would be encoded using combinations of triplets. The library is decoded by amplifying the encoded oligonucleotide strands by the polymerase chain reaction (PCR), followed by DNA sequencing. The PCR amplification step provides enough sensitivity to allow single bead decoding. If multiple beads are decoded, separate PCR amplifications must be performed on each bead. A disadvantage of this encoding strategy is that the peptide products must remain immobilized on the bead surface during biological assay. Interference from the oligonucleotide tags could bias binding assays. Further, DNA strands are sensitive to temperature, redox reagents, and strong acids and bases, and hence they are of limited use in the synthesis of nonpeptide combinatorial libraries.

2.5.2 Peptide Tags

In a manner analogous to the use of oligonucleotide tags, peptides have been used to encode combinatorial libraries prepared by split synthesis. Two distinct applications of peptide encoding have been reported.\(^{21,22}\) In the first approach, a bifunctional linker containing two orthogonal protecting groups is attached to a polystyrene resin. One of the protecting groups is acid labile and the other is removed by bases. The two sites on the linker serve as points of attachment for the peptide tag and the peptide ligand. A pair of alternating combinatorial syntheses is used to construct the ligand and tag on the solid support. The linker itself is acid labile, and is cleaved from the solid support prior to screening to yield a solution containing the coupled ligand/tag pairs. The active ligands are

![Figure 5 Encoding a solid-phase combinatorial library using molecular tags.](image-url)
isolated by affinity selection following biological assay. The identity of these active peptides is determined from Edman sequencing of the peptide tags.

Salmon et al. devised a novel orthogonal release approach to screening and identifying active peptides in combinatorial libraries. Instead of relying on separate ligands and tags, the method uses a single peptide for both functions. Peptides are synthesized on an orthogonal linker possessing three pH sensitive cleavage sites, such that each linker molecule incorporates three copies of the peptide. In the assay procedure, approximately 500 resin beads are placed into each well of a 96-well microliter plate. A pH 4.5 buffer is applied to the beads to release the first third of the immobilized peptide molecules from the linker. The filtrate from each well is screened for biological activity, and the beads in the active wells are redistributed into clean assay plates as one bead per well. The single beads are treated with dilute base and the second peptide molecule from the linker is screened for activity. The identity of the active peptide is determined through Edman sequencing of the remaining peptide attached to the linker. Peptide sequencing by electrospray ionization mass spectrometry (ESIMS) and tandem mass spectrometry (MS/MS) also has been reported.

2.5.3 Molecular Tags
To overcome the synthetic constraints imposed by the use of oligonucleotide and peptide tags, Still et al. developed a method for encoding combinatorial libraries using electrophoric tags. Electrophoric tags are halogen-substituted phenoxyalkyl alcohols and are analyzed during library decoding by gas chromatography (GC) with electron capture detection (ECD). Prior to attachment on a polystyrene resin, the tag molecule is derivatized with an oxidatively labile linker (3-methoxy-4-hydroxybenzoic acid), and the linker’s carboxylic acid group is converted to a diazoketone group. The derivatized tag is subsequently immobilized on the surface of the polystyrene resin through a metal-catalyzed carbene insertion reaction. The immobilized tags are extremely stable to the harsh conditions often encountered in organic synthesis, which has made this tagging technique ideally suited to the synthesis of nonpeptide combinatorial libraries.

A novel feature of the encoding strategy developed by Still et al. is that the molecular tags are coupled through oxidatively labile linkers, while ligands are attached using photolabile groups. Molecular tags and ligands are released from the polystyrene support by independent mechanisms, thus eliminating interference during assay and decoding. In addition, the high sensitivity of ECD requires only picomoles of tag molecules for analysis. Hence, only about 1% of the loading capacity of the resin is required for tagging, leaving the bulk of the resin surface available for ligand immobilization.

As with other chemical tagging strategies, the preparation of combinatorial libraries encoded with molecular tags involves alternating cycles of ligand synthesis and encoding reactions. The choice of tag molecules and the sequence of their immobilization are based on their order of elution by GC. Molecular tags based on dialkylamines also have been reported.

2.5.4 Radiofrequency Transponders
RF-encoded combinatorial chemistry makes use of miniature solid-state transponders to record encoding information during a split synthesis. These devices are encased in glass, which renders them inert to most organic reactions. Two types of RF transponder have been reported. One type of transponder is designed to receive, store, and emit binary encoded RF signals. The specific reagents used in each step of a split synthesis are assigned unique bar codes by a computer, and these are transmitted to the transponder during synthesis. The entire synthetic pathway for a compound can be read from the information stored on the device. The second type of RF transponder does not store encoded data, but rather emits a unique numeric identifier when passed over a scanning device. A computer is used to track the reaction history for this second type of transponder in a split synthesis. The main advantages of RF transponders are that the encoding process does not require additional chemical reactions, and library decoding does not involve analytical characterization of molecular tags.

Figure 6 RF encoding of a single combinatorial library member. Multiple resin beads contained within the reactor are treated as a single unit during synthesis.
Both types of transponder are physically handled in the same manner. A set of porous capsules is filled with an appropriate resin, and a microchip transponder is placed inside each one (see Figure 6). The capsules are sealed and treated as individual reactors in a split synthesis. Organic reactions may be performed using conventional laboratory glassware, and the capsules are easily manipulated manually, or with the aid of laboratory robots.

### 2.6 Solution-phase Synthesis

The application of liquid-handling robots to organic synthesis and the simultaneous design of apparatus for temperature control and agitation of multiple independent reaction vessels during the early to mid-1990s provided chemists with an attractive alternative to solid-phase combinatorial synthesis. Solution-phase synthesis is performed by reacting all possible combinations of a set of reagents in parallel. A primary advantage of solution-phase synthesis is that there is no need to develop strategies for the attachment of substituents to a solid support, or their subsequent cleavage.

Hence, lead times for reaction optimization are much shorter for solution-phase synthesis compared with SPS. Furthermore, solution-phase syntheses can be scaled to multi-milligram yields. Disadvantages of solution-phase synthesis are that the technique is limited to short reaction sequences, and the products can be difficult to purify. Most laboratories apply solution-phase synthesis to the generation of combinatorial libraries of discrete compounds, rather than mixtures. The population of solution-phase libraries is usually limited to only a few hundred compounds.

### 3 LIBRARY CHARACTERIZATION BY FOURIER TRANSFORM INFRARED SPECTROSCOPY

Infrared (IR) spectroscopy is a powerful sample characterization technique with broad application in organic and analytical chemistry. The mid-IR region provides both important functional group information (4000–1300 cm\(^{-1}\)) and structural information (1300–650 cm\(^{-1}\)). FTIR instruments are equipped with interferometers, which allow multiple spectral measurements of a sample to be made and averaged, and the resulting IR spectrum to be displayed in the frequency domain. The improvement in signal-to-noise that results from signal averaging affords FTIR instruments greater sensitivity than is possible with grating-based IR instruments. The high sensitivity of FTIR, its nondestructive nature, low cost, and ease of use make it ideally suited to reaction monitoring and final product characterization of combinatorial libraries.

While IR spectroscopy may be used quantitatively, its application to the characterization of organic molecules is usually qualitative. The widths of the bands in IR spectroscopy are quite narrow and lead to deviations from Beer’s law over wide ranges of absorption. If quantitation is desired, the IR bands monitored should be reasonably wide and well resolved from nearby absorptions so that an accurate integration can be performed. The identity of a compound usually is confirmed by verifying the presence or absence of characteristic absorption bands in the product’s IR spectrum. Changes in the intensity of specific bands in the IR spectra of reagents or product molecules are followed during reaction monitoring.

### 3.1 On-resin Analysis by Fourier Transform Infrared Spectroscopy

Rapid growth in the field of combinatorial chemistry during the mid-1990s lead to an increased interest in SPOS. The lengthy process of optimizing reaction strategies for use on solid supports has created the need for rapid and sensitive analytical techniques for monitoring solid-phase reactions. Ideally, a suitable technique for reaction monitoring would consume an insignificant amount of sample; involve little sample preparation; provide rapid analysis; possess high sensitivity; and have sufficient specificity to distinguish reagents from product. In traditional organic synthesis thin-layer chromatography (TLC) is the analytical technique of choice for monitoring reactions. FTIR spectroscopy has proven to be an equally capable technique for SPOS. Application of FTIR spectroscopy to reaction monitoring and final product characterization on solid supports is described in the following sections.

#### 3.1.1 Fourier Transform Infrared of Pressed Potassium Bromide Pellets

Many of the early pioneers of SPS relied extensively upon IR spectroscopy to characterize resin-bound compounds. Crowley and Rapoport quantitated the extent of chloromethylation of polystyrene resin based upon the H–C–Cl bending vibration at 1250 cm\(^{-1}\) in the preparation of resin linkers for the Dieckmann cyclization of mixed esters. Frechet and Schuerch characterized resin-bound intermediates by IR spectroscopy during a six-step synthesis of polystyrene linkers used in the SPS of oligosaccharides. Goldwater and Leznoff employed IR spectroscopy to characterize products from the SPS of monoester monoamides and monoester monoalcohols. Larsen et al. followed the stepwise SPS
of a peptide using Fourier transform Raman spectroscopy (FTRS). Narita et al.\textsuperscript{36,37} employed FTIR spectroscopy to characterize the conformation of peptides immobilized on polystyrene beads.

Preparation of samples for direct analysis by FTIR involves mixing approximately 10 mg of the resin beads with 190 mg of KBr, and compressing the mixture to form a pellet.\textsuperscript{38} The quality of the resulting pellet is highly dependent on the pressing technique used, and the best results are obtained if the pressing die is warmed to 50 °C. The IR spectra of resin-bound products are usually obscured by absorptions from the polymer matrix, and background subtraction of the resin matrix is required to obtain interpretable sample spectra.

There are a number of disadvantages to treating resin-bound compounds like conventional solid samples during their preparation for analysis by FTIR. First, the KBr pellet technique consumes too much material. A 10-mg sample of 50-µm diameter resin contains approximately 100000 beads, and most SPSs are carried out on less than 100 mg of resin. Second, this sample preparation technique is incompatible with mixture libraries prepared by split synthesis. The individual resin beads present in mixture libraries represent a number of unique products, and these must be characterized separately.

### 3.1.2 Single-bead Fourier Transform Infrared Microspectroscopy

Yan and Kumaravel\textsuperscript{39} developed the technique of single-bead Fourier transform infrared microspectroscopy (SBFTIRM) to overcome the limitations of conventional FTIR analysis of bead-bound combinatorial libraries. The instrumentation required for SBFTIRM consists of a conventional FTIR instrument equipped with an IR microscope accessory. The IR microscope includes an X–Y sample stage, a magnification objective, and a liquid-nitrogen-cooled mercury–cadmium–telluride (MCT) detector. Spectra may be obtained by conventional transmission mode, or by attenuated total reflectance (ATR). The latter technique detects only compounds on a resin bead’s outer surface, whereas transmission mode IR spectra represent compounds on the surface and interior porous regions of the resin.

Sample preparation in SBFTIRM is straightforward. A drop of resin suspension is withdrawn from the reaction solution and the resin beads are washed with organic solvent and briefly dried under vacuum. The beads are placed on a NaCl window mounted on the X–Y stage of the IR microscope. Spectra are recorded in transmission or ATR mode by averaging 64 scans from a single resin bead. The FTIR spectra of compounds obtained in this manner are complicated by absorbances from the resin matrix. The quality of single-bead IR spectra can be dramatically improved by flattening the beads to a thickness of 10–15 µm between a pair of NaCl windows.\textsuperscript{39} Comparison of the FTIR spectra obtained on a single Merrifield resin bead (Figure 7a) and a flattened bead (Figure 7b) illustrates the improvements in band shape and spectral resolution that result from the transmission of IR energy through a short, uniform pathlength.

SBFTIRM is superior to NMR and MS analyses in that the technique is extremely sensitive and does not require cleavage of the compound from the solid support. SBFTIRM is compatible with resin beads as small as

![Figure 7 SBFTIRM spectrum of (a) a single Merrifield bead and (b) a flattened bead. (Reprinted from B. Yan, G. Kumaravel, Tetrahedron, 52(3), 843–848 (1996), with permission from Elsevier Science Ltd.)](image-url)
50 µm in diameter, and the technique has a detection limit of approximately 100 pmol of bound compound.\(^{(40)}\) In addition, single-bead analysis by SBFTIRM produces spectra that are representative of the larger population of resin beads in SPS.

SBFTIRM has been used to measure the rates of a variety of organic reactions on solid-phase supports.\(^{(41–44)}\) These experiments have helped dispel a number of myths surrounding SPOS.\(^{(45)}\) Among the results are the following:

- the rates of organic reactions on solid supports are comparable to their counterparts measured in solution
- positioning the reactive site away from the bead surface through attachment of poly(ethylene glycol) spacers has no significant impact on the rates of organic reactions relative to rates measured on conventional resins
- comparison of the rates of solid-phase reactions monitored by transmission mode and ATR-mode SBFTIRM indicate that reaction kinetics on the bead surface and the bead interior are similar.

Overall, the technique of SBFTIRM is rapid, information rich, and has provided a greater understanding of SPOS.

### 3.1.3 Diffuse Reflectance Infrared Fourier Transform

Diffuse reflectance infrared Fourier transform (DRIFT) employing micro-sample-cups was developed by Deben et al.\(^{(46)}\) as an alternative to conventional methods of FTIR analysis of resin-bound compounds. The micro-DRIFT technique requires only one tenth of the amount of resin used to prepare KBr pellets, and is simpler to perform than SBFTIRM. Sample preparation involves grinding 0.5–1.0 mg of resin with 30 mg of KBr, transferring the mixture into a DRIFT microcup, and placing the microcup into a nitrogen-purged DRIFT cell in the sample compartment of the FTIR. The micro-DRIFT technique yields FTIR spectra that compare favorably with spectra obtained by SBFTIRM. This technique, however, is not compatible with the characterization of mixture libraries prepared by split synthesis.

### 3.1.4 Photoacoustic Fourier Transform Infrared

Gosselin et al.\(^{(47)}\) reported a simple, rapid, nondestructive technique to monitor solid-phase organic reactions based on photoacoustic Fourier transform infrared (PAFTIR) spectroscopy. PAFTIR spectroscopy measures the pressure variations of an inert gas above a sample that result from the sample’s absorption of modulated IR radiation. This absorbed radiation heats the boundary layer of gas above the sample and sets up a pressure wave that is detected by a sensitive microphone. Multiple scans are averaged, and the resulting spectrum is Fourier transformed to the frequency domain. In contrast to transmission, ATR, and DRIFT techniques, PAFTIR is not susceptible to interference from light scattering and reflection by the sample. Approximately 10 mg of resin is required to obtain a reasonable spectrum, and no additional sample preparation is required. The resin may be used in subsequent reactions following PAFTIR. PAFTIR is not compatible with split synthesis SPOS.

### 3.1.5 Fourier Transform Infrared of Pins

Characterization of compounds attached to polyethylene pins by ATR/FTIR has been described by Gremlich and Berets.\(^{(48)}\) In this technique, an internal reflectance probe is placed on a pin and pressed down to ensure good contact with the pin surface. Spectra are acquired in ATR mode and signal averaging is employed to improve the signal-to-noise ratio. The technique requires no sample preparation, is fast and nondestructive. Additional organic reactions may be performed on the pin surface following FTIR analysis.

### 3.1.6 Continuous Reaction Monitoring

Pivonka et al. developed a flow-through cell that allows solid-phase organic reactions to be monitored in situ by FTIR.\(^{(49)}\) The flow cell consists of a 50-µm thick Teflon® gasket sandwiched between two IR transparent windows as shown in Figure 8. Inlet and outlet ports allow organic solvents to be pumped through the cell. The entire cell is mounted on the X–Y stage of an IR microscope and spectra of individual resin beads may be recorded in transmission or ATR mode. The apparatus allows the FTIR analysis of multistep syntheses to be performed in real time.

Sample preparation involves placing a few resin beads near the center of the Teflon® gasket with the aid of a small drop of fluorolube gel. The flow cell is then assembled and positioned on the IR microscope. A series of solvents and reagents are passed through the flow cell, and FTIR spectra of the resin bead are collected at regular intervals during the synthesis. This approach to reaction monitoring has three advantages over SBFTIRM. First, continuous monitoring of reactions in situ does not require additional sample preparation. Second, this technique is compatible with monitoring organic reactions with short half-lives. Lastly, analysis of the same bead throughout an experiment makes it possible to enhance the FTIR spectra of resin-bound
3.2 Off-resin Analysis by Fourier Transform Infrared Spectroscopy

Development of MS and NMR-based techniques for characterizing solution-phase combinatorial libraries has overshadowed analysis of these types of samples by FTIR. Indeed, widespread application of FTIR in combinatorial chemistry has been limited to the analysis of solid-phase libraries. Considerable research during the 1980s and early 1990s led to the development of suitable interfaces for coupling HPLC with FTIR spectroscopy. Many of the approaches to high-performance liquid chromatography/Fourier transform infrared (HPLC/FTIR) could be automated to perform flow-injection FTIR, or HPLC/FTIR analysis of solution-phase libraries. A description of several flow-through and solvent-elimination HPLC/FTIR interfaces available is given next.

3.2.1 Flow-through Fourier Transform Infrared Interfaces

A flow-through HPLC/FTIR interface provides a direct link between the liquid chromatograph and the IR spectrometer. Effluent from an HPLC column passes through a flow cell mounted within the sample compartment of an IR spectrometer. This arrangement allows IR spectra of eluting components to be recorded in real time. No sample preparation is required and solutes may be recovered after analysis. The major disadvantages of flow-through interfaces are that they suffer from low sensitivity, and are prone to losses of solute information due to regions of solvent opacity in the mid-IR.

3.2.2 High-performance Liquid Chromatography/Fourier Transform Infrared Flow Cells

The first flow cells designed for HPLC/FTIR consisted of a spacer sandwiched between a pair of NaCl or KBr windows through which the column effluent passed. These early designs, however, were of little practical value for routine compound analysis. Many of the solvents used in liquid chromatography (LC) absorb across regions of the mid-IR and interfere with solute detection. In addition, the use of strong IR-absorbing solvents severely limits the cell pathlengths that can be tolerated, which further reduces solute sensitivity. The use of IR-transparent solvents, such as CHCl₃ and CDCl₃, as eluants in normal-phase HPLC improves solute detection by FTIR, but limits the types of solutes that may be characterized by the technique. Microbore (1 mm i.d.) HPLC columns operate at lower flow rates than analytical (4.6 mm i.d.) columns, thereby increasing solute concentrations in the mobile phase 20-fold. The use of microbore columns can help overcome the sensitivity limitations associated with the use of short pathlength flow cells in HPLC/FTIR. A schematic diagram of a zero dead volume flow cell designed for microbore HPLC/FTIR is shown in Figure 9. This flow cell has a pathlength of 0.45 mm, an internal volume of 0.33 µL, and can detect less than 50 ng of 2,6-di-tert-butylphenol at 3641 cm⁻¹.

Flow cells designed for reversed-phase HPLC/FTIR are based on ATR technology and constructed with ZnSe cell windows. In contrast to the HPLC/FTIR flow cells, IR radiation passing through an ATR cell penetrates only a few wavelengths into the exterior sample region per internal reflection. Thus, the effective pathlength of ATR flow cells is short enough to keep interference from water absorption to an acceptable level. McKittrick et al.
compared the performance of micro and ultramicro cylindrical internal reflectance (CIRCLE) cells for the detection of caffeine and theophylline by reversed-phase HPLC/FTIR. The micro CIRCLE cell had an internal volume of 24 µL and an effective pathlength of 4.65 µm, while the ultramicro CIRCLE cell had an internal volume of 1.75 µL and an effective pathlength of 3.18 µm. These types of flow cell, however, suffer from poor sensitivity. The detection limits for caffeine with the micro and ultramicro flow cells were 0.1 mg and 0.5 mg, respectively.

3.2.3 Solvent-elimination Interfaces for High-performance Liquid Chromatography/FTIR

Solvent-elimination interfaces for HPLC/FTIR overcome the disadvantages of solvent opacity and poor solute sensitivity characteristic of flow-through interfaces by removing the liquid solvent from solutes of interest prior to IR spectroscopy. These interfaces are compatible with many modes of chromatography, including normal-phase, reversed-phase, and gradient HPLC. The solvent elimination process concentrates solutes prior to analysis, and hence achieves high sensitivities with FTIR spectroscopy. The major disadvantages of solvent-elimination interfaces stem from their complexity and incompatibility with real-time analysis. Furthermore, volatile solutes may be lost during desolvation, and thermally labile compounds are susceptible to degradation. When used with aqueous solvents, these interfaces cannot tolerate flow rates greater than 0.5 mL min⁻¹. Three solvent-elimination interfaces for HPLC/FTIR are described below.

3.2.4 The High-performance Liquid Chromatography/Diffuse Reflectance Infrared Fourier Transform Interface

The first high-performance liquid chromatography/diffuse reflectance infrared Fourier transform (HPLC/DRIFT) interface was developed by Kuehl and Griffiths in the late 1970s. In this technique, the mobile phase exiting the column is deposited into a series of diffuse-reflectance cups filled with KBr. The chromatographic solvent is allowed to evaporate, and the DRIFT spectra of the solute residue on the KBr substrate are recorded. The HPLC/DRIFT technique provides greater solute sensitivity than flow-through interfaces, but does not allow continuous analysis of the chromatographic eluant. Further, the quality of DRIFT spectra is dependent on the particle size of the KBr substrate, which can change during solvent evaporation. Conventional HPLC/DRIFT interfaces are not compatible with reversed-phase HPLC, because the KBr substrate is water soluble. However, Kalasinsky et al. demonstrated that water could be eliminated from the mobile phase through post-column treatment with 2,2-dimethoxypropane. Water reacts with
2,2-dimethoxypropane stoichiometrically to yield two moles of methanol and one mole of acetone. Alternatives to chemical removal of water from reversed-phase elu-

3.2.5 Mono-disperse Aerosol Generation Interface for Combining High-performance Liquid Chromatography with Fourier Transform Infrared

The mono-disperse aerosol generation interface for combining high-performance liquid chromatography with Fourier transform infrared (MAGIC/HPLC/FTIR) was adapted from a similar device for coupling HPLC with MS. A schematic of an HPLC system equipped with this interface is shown in Figure 10. During operation, the HPLC mobile phase exiting the column is converted to a uniform stream of droplets in the aerosol generator. Dispersion of the droplets is achieved with the aid of a stream of helium gas. Solvent is removed by evaporation at ambient temperature, and solvent vapor and helium gas are removed from the stream of solute particles under vacuum. Solute particles are collected on the surface of an IR-transparent collection plate, which is moved continuously during analysis. IR spectra of the deposited solutes are collected off-line using a separate reading device mounted in the sample compartment of the IR spectrometer (see Figure 11c). Spectra obtained in this manner are susceptible to Christiansen scattering (i.e. a sudden rise on one side of an absorption band and a tailing on the other side) depending on the particle size of the deposited solute and refractive index changes that may occur in the vicinity of an absorption band. A representative FTIR spectrum of anthracene is shown in Figure 12.

A continuously recording interface for HPLC/FTIR is available commercially. The commercial instrument replaces the heated gas nebulizer in Gagel and Bie-

Figure 10 MAGIC/HPLC/FTIR. (Reproduced with permission from V.E. Turula, J.A. de Haseth, Anal. Chem., 68, 629–638 (1996). Copyright 1996 American Chemical Society.)
of an aluminum mirror. Detection limits are in the 10−100 ng range. This interface is compatible with both normal- and reversed-phase HPLC, but only volatile buffers may be used in the mobile phase. Somsen et al. incorporated a liquid–liquid extraction step upstream of solute deposition to make the interface compatible with the use of nonvolatile buffers (e.g. 10 mM potassium phosphate) in reversed-phase eluants.

4 LIBRARY CHARACTERIZATION BY MASS SPECTROMETRY

MS is one of the most sensitive analytical techniques available for the characterization of organic compounds. Modern mass spectrometers are capable of detecting low-molecular-weight organic compounds in the picomole to femtomole range. In addition to its high sensitivity, MS provides important molecular-weight and structural information that can be used to monitor reactions, or confirm the identity of final products. Specific compounds may be readily confirmed by noting the presence of characteristic molecular ions in a sample’s mass spectrum. The inherent simplicity of MS data makes it possible to develop sophisticated algorithms to interpret
the mass spectra of combinatorial libraries in an efficient manner. Indeed, a number of commercial software packages are available for processing MS data and reporting sample results in condensed form. The development of similar tools for FTIR and NMR data reduction has languished due to the complexities involved in interpreting these types of spectra. Together these attributes have contributed to the widespread acceptance of MS among combinatorial chemists.

4.1 On-resin Analysis by Mass Spectrometry

MS can only detect ions in the gas phase. Compounds originating from SPS must be cleaved from the surface of the solid support prior to MS analysis, and the cleavage step can take up to 24 h to perform. From this perspective, MS is not as convenient a technique for reaction monitoring in SPS as SBFTIRM and magic-angle spinning (MAS) NMR spectroscopy. Nonetheless, the high sensitivities that can be achieved with MS make the technique ideally suited to the analysis of single resin beads. Matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI/TOFMS) has emerged as the MS technique of choice for characterizing peptides and low-molecular-weight organic compounds covalently bound to solid-phase supports.

4.1.1 Matrix-assisted Laser Desorption/Ionization Time-of-flight Mass Spectrometry

Preparation of resin-bound samples for MALDI/TOFMS is tedious and difficult to fully automate. Before compounds obtained from SPS can be analyzed, they must be cleaved from the solid support and combined with a suitable ultraviolet (UV) absorbing matrix. The matrix is required for the matrix-assisted laser desorption/ionization (MALDI) process, and sample ionization efficiencies can be highly matrix dependent. Typical matrices employed in MALDI/TOFMS include 2,5-dihydroxybenzoic acid, α-cyano-4-hydroxycinnamic acid, and 3,5-dimethoxy-4-hydroxycinnamic acid. Procedures for cleaving a resin-bound compound depend on the nature of the linker employed in SPS. Compounds immobilized through acid-labile linkers can be removed by treating the resin with a solution of 1–2% trifluoroacetic acid (TFA) in dichloromethane. A more convenient method is to expose the resin beads to the acidic vapor produced from a solution of 15% TFA in dichloromethane for 3–5 min. Base-labile linkers can be cleaved using 1–2% ammonia in tetrahydrofuran (THF). Photo-labile linkers require treatment with UV light to cleave resin-bound compounds.

The application of MALDI/TOFMS to the characterization of peptide libraries has been reported by a number of research groups. High-quality MALDI/TOFMS can be obtained from as little as 2–5% of the total peptide isolated from a single resin bead. In addition, MALDI/TOFMS may be used to assess the quality of a library by revealing the presence of deletion peptides, the products of side reactions and incomplete-deprotection products. Analysis of peptide libraries by imaging time-of-flight secondary ion mass spectrometry (TOF/SIMS) has also been reported.

The characterization of nonpeptide bead-bound combinatorial libraries by MALDI/TOFMS requires the same sample preparation involved in the analysis of peptide libraries. Zambias et al. characterized a peptoid attached via a Rink amide linker to a polymeric bead by MALDI/TOFMS employing 2,5-dihydroxybenzoic acid as a matrix. This same matrix was employed by Haskins et al. to characterize the individual components of a five-member combinatorial library. Brummel et al. reported that the MALDI/TOF mass spectrum of an angiotensin II antagonist (see Figure 13) synthesized on a polystyrene resin compared favorably with the electrospray ionization (ESI) mass spectrum of the same compound. Quantitative MALDI/TOFMS has been applied to study the incorporation of combinatorial libraries of porphyrins and peptide–DNA hybrids into liposome membranes. An automated system for the analysis of combinatorial samples by matrix-assisted laser desorption/ionization Fourier transform mass spectrometry (MALDI/FTMS) was developed by Tutko et al. The automated MALDI/FTMS instrument allows the characterization of 20 samples per hour and can be used for accurate mass determinations and MS/MS.

4.2 Off-resin Analysis by Mass Spectrometry

MS is typically applied to the characterization of libraries of compounds that have been cleaved from solid-phase resins, or that were synthesized in parallel by solution-phase techniques. Demands for high mass resolution, sensitivity, and speed of analysis place a number of constraints on instrument design. Automation requires that the samples be swept into the mass spectrometer in a liquid stream, as exemplified by flow injection analysis mass spectrometry (FIA/MS) and liquid chromatography/mass spectrometry (LC/MS) techniques. The design of interfaces that can both accommodate the introduction of analytes in solution and generate gas-phase ions suitable for mass analysis and detection is central to the successful application of MS in combinatorial chemistry.

4.2.1 Liquid Chromatography/Mass Spectrometry Interfaces

All LC/MS interfaces are designed to perform two basic tasks. First, they provide a mechanism for stripping solvent molecules from solutes present in the sample. These solute molecules are then converted into gas-phase ions prior to entering the mass analyzer. Depending on the design of the interface, the desolvation and ionization processes may occur under conditions of low vacuum or atmospheric pressure. The two most common sample introduction techniques used in the analysis of libraries of compounds present in solution are ESI and atmospheric pressure chemical ionization (APCI).

In the ESI process, the liquid sample is pumped through a narrow-bore capillary whose outlet is held at a potential of a few kilovolts relative to an opposing counter-electrode. A volatile electrolyte generally is introduced into the sample to increase the sample’s ionic strength. The liquid becomes charged as it emerges from the electrospray capillary, and coulombic repulsion causes the stream to spread out as a plume of charged droplets. The mechanism leading to ion formation in electrospray is not well understood, but may be regarded as a process wherein charged droplets decrease in size through both evaporation and coulombic repulsive forces. Eventually these highly charged droplets reach a radius at which the electrical field gradient is large enough for ionized solute molecules to desorb from the droplet surface. The probable mechanisms involved in ESI have been described by Fenn and Kebarle and Tang.

A schematic diagram of a liquid chromatography/electrospray ionization (LC/ESI) interface is shown in Figure 14(a). ESI takes place at atmospheric pressure, and the sample ions formed are directed through a small orifice and a series of skimmers into the vacuum region of the mass spectrometer. An annular sheath gas surrounding the spray needle may be applied to enhance...
the desolation process. The electrospray process is a soft ionization technique, yielding primarily \([M + H]^+\) or \([M - H]^-\) ions even with thermally labile and non-volatile molecules. In addition, ESI can generate multiply charged ions, which makes the technique well suited to the analysis of biomolecules. Electrospray interfaces are generally operated at flow rates of 1–200 µL min\(^{-1}\) to the analysis of biomolecules. Electrospray interfaces charged ions, which makes the technique well suited for volatile molecules. In addition, ESI can generate multiply charged ions that are observed in ESI mass spectra.

4.2.2 Electrospray Ionization Mass Spectrometry

ESIMS is well suited to the analysis of low-molecular-weight (e.g. 10–1000 Da) organic compounds containing ionizable functional groups and large molecules (e.g. \(>10^3\) Da) with moderate to high polarity. It is not surprising, therefore, that ESIMS is the ionization technique most often applied to the MS characterization of combinatorial libraries. Analysis of nonpeptide libraries by ESIMS has focused mainly on the characterization of single compounds cleaved from individual resin beads \((87–89)\) or single compounds obtained from parallel synthesis \((90,91)\). The ESIMS spectra of low-molecular-weight organic compounds generally are characterized by singly charged molecular ions, and multiply charged ions are only rarely observed. Compounds containing basic functional groups yield intense positively charged molecular ions with little fragmentation. Hydrophobic molecules are more difficult to ionize by addition of a proton in ESIMS, and hence have a higher tendency to fragment.

Dunayevskiy et al. \((92)\) employed ESIMS to study the composition of six sub-libraries synthesized to mimic the diversity present in a 65 341 component mixture library. Analysis of the 36–55 member sub-libraries provided qualitative information on the yields of synthetic reactions used to generate the mixture library, and hence insight into the library’s actual composition. This work illustrated a number of difficulties that may be encountered when...
characterizing mixtures of small organic molecules by ESIMS. First, peak intensities do not directly correlate with sample concentration due to differences in ionization efficiency among organic compounds present in mixtures. Furthermore, polar solvents such as dimethyl sulfoxide (DMSO), used to prepare combinatorial libraries for biological testing, have a tendency to form intense adduct ions with library compounds. Complete suppression of product molecular ions in a combinatorial library by DMSO adduct ions has been reported by Kyranos and Hogan. Separation of the solute from the solvent by reversed-phase chromatography prior to MS analysis is an effective means of eliminating DMSO adduct formation.

The likelihood of a small-molecule mixture library containing isobaric compounds increases as the population of the library grows, hence direct application of ESIMS with nominal mass resolution to large mixture libraries is not practical. The instrumentation and data precision requirements for the MS determination of structures from combinatorial mixtures have been described by Blom. In addition, Hughes devised a rules-based strategy for designing combinatorial syntheses such that libraries of low-molecular-weight organic molecules always contain unique nominal product masses.

ESIMS is an extremely useful technique for the characterization of peptide libraries containing mixtures. Metzger et al. were the first to apply ion-spray and ESIMS to the analysis of synthetic peptide libraries. Side-reactions during SPPS can lead to peptide libraries that deviate significantly from expected molar composition. MS is ideally suited to peptide analysis, because it can readily distinguish between peptides differing by as little as one amino acid. While a number of MS ionization techniques are available for peptide analysis, many suffer from ion suppression effects. Ionization of some components present in a mixture may be partially or completely suppressed, even though the same compounds yield intense ions when analyzed separately. Ionization yields for individual peptides present in mixtures with ESIMS, however, have been reported to be nearly identical. Lambert et al. reported that a single peptide possessing a unique mass may be identified from a library containing up to 100,000 peptides using a combination of LC/ESIMS with selected ion monitoring. The feasibility of characterizing peptide mixtures by MS has been explored mathematically using computer simulations of mass spectra for peptides containing 2–7 amino acids. ESIMS also has been used to automate the purity assessment of synthetic peptides. The total ionizable material present in a sample is compared with the intensity of the target peptide and each of the identifiable contaminants present in order to arrive at an estimation of sample purity.

4.2.3 Atmospheric Pressure Chemical Ionization Mass Spectrometry

Moderately polar compounds within a mass range of 100–1000 Da ionize readily by APCI. APCI generally produces greater fragmentation and fewer multiply charged ions than ESI does. While fragment ions in a mass spectrum can complicate spectrum interpretation, their presence often helps confirm structure identity. These characteristics make APCI well suited to the identification of nonpeptide organic compounds. The ionization process in APCI can produce both positively and negatively charged molecular ions, and predicting the relative intensities of the two for a given compound can be difficult. Iwabuchi et al. examined the intensities of the molecular ions observed in positive-ion and negative-ion mode APCI for a series of hydroxymethylglutaryl–Coenzyme A reductase inhibitors. Lipophilic compounds in the series gave more intense molecular ions in positive-ion mode, while hydrophilic compounds gave more intense negatively charged molecular ions. Further, it is not often easy to predict whether APCI or ESI will be better suited to a given combinatorial library. Hence the designs for automated systems for high-throughput library characterization often make provision for both types of ionization technique in conjunction with positive and negative ion detection. Positive-ion mode APCIMS has been applied to the characterization of a variety of organic compound classes, including quinolones, pyrazoles, and dihydropyridones.

4.2.4 Tandem Mass Spectrometry

MS/MS is based on a simple fragmentation experiment in which a parent molecular ion dissociates into a corresponding product ion and neutral fragment molecule. The parent molecular ion may be positively or negatively charged, and the product ions produced have the same charge as the parent ion. MS/MS historically has been performed using triple quadrupole instruments, wherein the first and third quadrupoles are used to scan parent and product ion masses, and the intermediate quadrupole is employed as a collision chamber. Fragmentation of parent ions emitted from the first quadrupole is achieved through a process known as collision-induced dissociation (CID). Argon, nitrogen, methane, or ammonia gas are introduced individually or as mixtures into the second quadrupole. Collisions between parent ions and target gas molecules increase the internal energy of the parent ions. This collisional activation is followed by fragmentation into product ions and neutral fragment molecules. MS/MS may also be performed on ion-trap mass spectrometers. When carried out on ion-trap instruments, these experiments involve tandem
operations over time in the same space, whereas MS/MS experiments on triple quadrupole instruments involve tandem operations in different regions of space.

There are three basic types of MS/MS experiments: the product-ion scan, the neutral-loss scan, and selected reaction monitoring. A description of each of these experiments carried out on a triple-quadrupole instrument is given below. The product-ion scan provides a fragmentation mass spectrum of a single parent ion. The \( m/z \) of the parent ion is fixed by the first quadrupole, and the masses of all of the product ions formed from CID of the parent in the second quadrupole are scanned by the third quadrupole. A product-ion scan can be used to distinguish between multiple components introduced directly into the mass spectrometer as a mixture, or as a single band eluted during a chromatographic separation. A neutral-loss scan involves setting the first and third quadrupoles such that they scan for a constant difference in mass between the parent and product ions. The first quadrupole passes a select range of incoming parent ions into the collision region defined by the second quadrupole. Of the product ions generated through CID, only those with a specific mass difference from their respective parent ions are scanned by the third quadrupole. The mass difference between scans of the first and third quadrupoles equals the mass of the neutral fragment from CID of the parent ions. The neutral-loss experiment is used to confirm the presence of specific functional groups that are known to yield characteristic neutral loss molecules, such as \( \text{CO}_2 \) from carboxylic acids, or \( \text{NO} \) radicals from nitroaromatic compounds. A selected reaction monitoring experiment is performed by fixing the first quadrupole to pass a single parent ion to the collision chamber, and setting the third quadrupole to pass only one product ion fragment. While selected reaction monitoring provides less structural information than the other two MS/MS experiments, the technique delivers greatly enhanced sensitivity. The sensitivity enhancement results from a decrease in instrument noise, and the selected reaction monitoring experiment is best suited to the analysis of trace amounts of compound, such as single-bead characterization.

While MS/MS experiments can be performed on ion-trap instruments, the processes involved differ from those executed on triple-quadrupole mass spectrometers. For example, a product-ion scan carried out on an ion-trap mass spectrometer involves scanning the RF voltage to eject all ions in the trap, up to but not including the ion of interest. These trapped ions then undergo collision with a background gas inside the ion-trap chamber. The product-ion spectrum is recorded by ramping the RF voltage a second time to eject product ions from the trap. A distinct advantage of ion-trap instruments is that a product ion from the initial CID can be trapped and subjected to an additional CID cycle, and this process may be repeated through many generations of product ion. The ability to perform such MS\(^n\) experiments on ion-trap mass spectrometers provides the combinatorial chemist with a powerful tool for structure elucidation.

MS/MS has a number of possible applications to combinatorial chemistry, including structure characterization, identification of side products, deconvolution of isobaric mixtures, single-bead analysis, and library decoding. Keough et al.\(^{108}\) employed a hybrid magnetic sector/orthogonal acceleration single-pass time-of-flight (TOF) mass spectrometer to measure the exact masses of product ions formed during MS/MS studies of compounds.

![Figure 15](image.png)
from combinatorial libraries. In this work, the combination of exact mass measurement with MS/MS proved crucial to characterizing a major side-product present in a combinatorial sample, and differentiating between isobaric residues in peptides. Pomerantz et al. developed a MS/MS procedure that allows sequence analysis of mixtures of closely related oligonucleotides. Oligonucleotide sequencing involves performing a product-ion scan on each of the parent ions observed in the sample mixture. Mixtures containing oligonucleotides with the same mass yield product-ion mass spectra with partially overlapping signals. Proper interpretation of these spectra requires application of special algorithms, which are based on fragment-ion abundance patterns observed in sequencing of single oligonucleotides. The product-ion spectrum of two isomeric oligonucleotides is shown in Figure 15. MS/MS has also been used to decode secondary amine tags cleaved from resin beads following SPOS. In this example, a separation step was required to resolve isobaric masses prior to MS/MS in parent-ion scanning mode. Dansylated secondary amine tags could be detected unambiguously at the femtomole level, making the technique compatible with decoding of single resin beads.

5 LIBRARY CHARACTERIZATION BY NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

NMR spectroscopy is an information-rich technique for probing the structure of organic compounds. NMR spectroscopy can be used to differentiate between most structural, conformational, and optical isomers. The chemical shift information and coupling constant parameters provided by 1H NMR allow specific protons within an organic molecule to be assigned unambiguously. By performing heteronuclear 1H/13C shift and homonuclear shift correlated experiments, the exact structure of an organic molecule may be determined. In contrast to MS, NMR spectroscopy is a noninvasive and nondestructive technique. A sample may be recovered after a NMR experiment and used in subsequent analyses.

5.1 On-resin Analysis by Nuclear Magnetic Resonance Spectroscopy

Because it is a powerful tool for structural characterization of small organic molecules, there has been significant interest in the application of NMR spectroscopy to combinatorial chemistry. However, conventional NMR techniques are only compatible with homogeneous samples. Hence, characterization of compounds originating from SPS by standard NMR requires that the products be cleaved from the solid support prior to analysis. This presents a significant barrier to the characterization of resin-bound intermediates and reaction monitoring by NMR. Two sample-handling techniques that are amenable to the NMR analysis of resin-bound compounds are standard NMR using gel-phase samples, and MAS NMR. These gained wide acceptance within the combinatorial chemistry community during the 1990s and are discussed below.

NMR spectroscopy is most effective when the spectra of organic compounds possess good spectral resolution (i.e. narrow linewidths). There are two major factors that work to broaden the linewidths observed in NMR. The first of these is magnetic susceptibility inhomogeneity. All compounds possess an inherent magnetic susceptibility, which is a measure of how the compound affects a surrounding magnetic field. In an NMR experiment, a homogeneous sample will produce a uniform change in the applied magnetic field, and this can be corrected by a process called “shimming”. A resin-bound compound, however, is heterogeneous, and possesses regions of differing magnetic susceptibility that cannot be corrected by shimming. These magnetic susceptibility mismatches result in broadening of the normal NMR linewidths. Second, significant rotational freedom is required to overcome the dipolar splittings and chemical shift anisotropy present in rigid molecules.

The quality of NMR spectra obtained with solid-phase resins depends primarily on the resin structure, with choice of solvent playing a secondary role. Many of the resins used in SPS are based on cross-linked polystyrene that is functionalized with linker molecules attached to the polymer surface through tethers of varying length. The length of the tether influences the mobility of compounds attached to the resin. Tentagel™ resins have the longest tethers, and hence provide the narrowest observed NMR line widths. Wang type resins have short tethers and restrict the mobility of attached compounds. Compounds attached directly to polystyrene with no tether produce NMR spectra of poor quality. The shorter the tether on the polymer support, the more important proper choice of solvent becomes to produce quality NMR spectra. Resins swell to different degrees in various solvents, and the greater the extent of swelling the narrower the NMR line widths will be. Chloroform-d, dichloromethane-d2, benzene-d6, dimethylformamide-d7, and THF-d8 all provide significant swelling of polystyrene-based resins. Dichloromethane-d2 is generally preferred as a solvent because it provides the highest degree of swelling and its high volatility facilitates recovery of the resin after analysis. Methanol-d4, D2O, acetonitrile-d3, and dimethylsulfoxide-d6 do not appreciably swell polystyrene-based resins and are poor solvent choices for monitoring SPS by NMR.
5.1.1 Gel-phase Nuclear Magnetic Resonance

While $^1$H NMR is sufficiently sensitive to permit rapid analysis of solid-phase reactions, the signals obtained from resin samples by the gel-phase approach are typically too broad to be useful for structural determinations. Standard NMR of gel-phase samples is generally limited to the detection of heteronuclei such as $^{13}$C, $^{19}$F, $^{15}$N, and $^{31}$P, where there is significantly greater chemical shift dispersion than in $^1$H NMR. The linewidths observed in $^1$H NMR of gel-phase samples are typically greater than 100–300 Hz.

Gel-phase NMR spectra are obtained using conventional NMR sample tubes and high-resolution NMR spectrometers. Sample preparation involves placing between 50 and 100 mg of resin in a 5-mm NMR tube and adding sufficient deuterated solvent (0.2–0.3 mL) to cover the solid sample. Sonication or vortexing of the tube’s contents may be necessary to achieve a uniform gel. Solvent molecules entrained in a different environment within the solvent-swollen polymer matrix can lead to a second set of resonances in the NMR spectra of the gel samples. This can be corrected by using a significant excess of solvent, or by preswelling the resin with the solvent prior to placing it into the NMR tube.

Gel-phase $^{13}$C-NMR was employed extensively during the 1970s and early 1980s as an analytical technique to follow SPPS. Sternlicht et al. pioneered gel-phase $^{13}$C-NMR to characterize amino acids bound to cationic exchange resins. Leibfritz et al. employed gel-phase $^{13}$C-NMR in conformational studies on polypeptides bound to poly(oxyethylene) supports. The first application of gel-phase NMR to follow resin-bound intermediates in SPS was reported by Epton et al. in 1980. In this work, the step-wise synthesis of polypeptides on a phenolic cross-linked poly(acryloyl morpholine)-based matrix was monitored by recording the $^{13}$C-NMR spectra of the resin following purification by recrystallization. The choice of the resin matrix was based on its superior swelling characteristics over poly(styrene) matrices in polar organic solvents, such as DMSO, that solubilize peptides well. Giralt et al. followed the step-wise synthesis of the peptide $\text{H—Asn—(N—Me)−Ala—Thr—NH}_2$ on a benzhydrylamine resin by gel-phase $^{13}$C-NMR. Both Epton et al. and Giralt et al. reported that narrow signals are obtained for carbons that are further away from the polymer backbone, while the NMR signals for carbons close to the backbone broaden and diminish in intensity as the peptide chain grows. The latter is attributed to decreased mobility of nuclei nearer the support.

Application of gel-phase NMR in SPOS was first reported by Manatt et al. in 1980. In 1982, Jones et al. employed gel-phase $^{13}$C-NMR to characterize resin-bound intermediates from the SPOS of insect pheromones. As with gel phase $^{13}$C-NMR of peptides, the

![Figure 16](https://example.com/figure16.png) Fast $^{13}$C-NMR monitoring of a stepwise reductive amination sequence. (Reproduced with permission from G.C. Look, C.P. Holmes, J.P. Chin, M.A. Gallop, *J. Org. Chem.*, 59, 7588–7590 (1994). Copyright 1994 American Chemical Society.)
resonances of carbon atoms close to the polymer backbone were observed to be broadened relative to those associated with side chains of the resin-bound intermediates. Blossey et al.\textsuperscript{(119)} reported the gel-phase \(^{13}\)C-NMR characterization of resin-bound steroids obtained by SPOS on dehydrocholic and cholic acids immobilized on chloromethylated poly(styrene–2% divinylbenzene). Correlation with solution-phase \(^{13}\)C-NMR spectra permitted complete assignment of each of the resonances observed in the gel-phase \(^{13}\)C-NMR spectra of the resin-bound steroids.

Gel-phase \(^{13}\)C-NMR involves averaging thousands of transients to improve signal-to-noise, making the technique impractical for monitoring reactions in real time. The long analysis times required in \(^{13}\)C-NMR are primarily due to the low natural abundance of the \(^{13}\)C isotope. By using \(^{13}\)C enriched reagents, Look et al.\textsuperscript{(120,121)} have reported obtaining high-quality NMR spectra from as few as 64 transients. Fast \(^{13}\)C-NMR analysis requires as little as 20 mg of resin, and can be performed within 15–30 min with most of this spent drying the resin sample. Representative \(^{13}\)C-NMR spectra from a stepwise reductive amination sequence are shown in Figure 16. The limited availability of \(^{13}\)C-enriched intermediates may make this characterization technique impractical for some SPOS applications.

Manatt et al.\textsuperscript{(122)} incorporated \(^{19}\)F nuclei into amino-protecting groups and used these to monitor SPPS by gel-phase \(^{19}\)F-NMR. These intermediates were immobilized on 1\% cross-linked, chloromethylated polystyrene, and provided reasonably narrow NMR linewidths. Loadings as low as 0.005 mequiv g\(^{-1}\) could be detected by gel-phase \(^{19}\)F-NMR.

Swayze\textsuperscript{(123)} incorporated isotopically enriched \([^{15}\text{N}]\text{ala}-\text{nine in the synthesis of a combinatorial library of 3,4,8-}
trisubstituted 1,4-diazabicyclo[3,4,0]nonan-2-one compounds. The labeled amino acid nitrogen was involved in the formation of the key heterocyclic ring via an intramolecular Mitsunobu reaction, the formation of which was monitored by gel-phase \(^{15}\)N-NMR.

Gel-phase \(^{31}\)P-NMR has two advantages over \(^{13}\)C-NMR for characterizing phosphorus-containing compounds immobilized on solid supports. First, the 100% natural abundance of the \(^{31}\)P isotope makes the technique 383 times more sensitive than \(^{13}\)C-NMR. Spectra can be obtained in as little as 10 min using the same sample preparation techniques described for gel-phase \(^{13}\)C-NMR. Second, most polymer resins used in SPS do not contain phosphorus, and hence do not interfere with the observed resonances in \(^{31}\)P-NMR. Bardella et al.\textsuperscript{(124)} were the first to apply \(^{31}\)P-NMR to the characterization of oligonucleotides prepared by SPS. The technique has also been applied to monitor the SPPS of phosphotyrosine-containing peptides.\textsuperscript{(125)} Johnson and Zhang\textsuperscript{(126)} used gel-phase \(^{31}\)P-NMR to monitor the Horner–Wadsworth–Emmons synthesis of a combinatorial library of alkenes. Completion of this reaction is indicated by the disappearance of the multiplet at \(^{\delta}\) 22 due to the resin-bound diethylphosphonoacetamide starting material and the simultaneous appearance of a broad resonance for diethylphosphonate at \(^{\delta}\) 0.

Quarrell et al.\textsuperscript{(127)} studied the \(^{31}\)P-NMR spectra of \(\alpha\)-triphenylphosphonium-p-toluic acid bromide in solution and immobilized on Tentagel\textsuperscript{TM} resin in order to characterize the mobility of compounds immobilized on this widely used solid-phase support.

5.1.2 Magic-angle Spinning Nuclear Magnetic Resonance

In solution, rapid isotropic motion averages the dipolar splittings and chemical shift anisotropy to zero, which yields sharp lines in the corresponding NMR spectrum. In solids, both the dipolar coupling and the chemical shift anisotropy contain an angular dependence of the form \((3 \cos^2 \theta - 1)\). This angular dependence becomes zero when \(\theta\) equals roughly 54.73\(^{\circ}\), hence this angle is referred to as the “magic angle”.

Characterization of cross-linked polystyrene gels by \(^{1}H\)-MAS NMR was first reported in the mid-1980s.\textsuperscript{(128)} A lack of suitable techniques for determining the structure of resin-bound compounds led to the investigation of \(^{1}H\) MAS NMR as an analytical tool for SPOS beginning in the mid-1990s. The acquisition of high-resolution \(^{1}H\)-MAS NMR spectra, however, would not have been possible were it not for the development of NMR probes that combined the use of both MAS and “magnetic-susceptibility-matched” materials. Indeed, the first reported 500 MHz \(^{1}H\)-NMR spectrum of a resin-bound compound was recorded using the Nano-NMR\textsuperscript{TM} probe commercialized by Varian Instruments (Palo Alto, California).\textsuperscript{(129)} A comparable high-resolution MAS probe is available from Bruker (Rheinstetten, Germany). A comparison of a 16-scan 500 MHz \(^{1}H\)-NMR spectrum of a resin-bound compound obtained using a conventional 5-mm liquids probe with that obtained by \(^{1}H\)-MAS NMR using a Nano-NMR\textsuperscript{TM} probe is shown in Figure 17. In addition to providing a significant improvement in resolution through removal of magnetic susceptibility line broadening, the MAS probe required only one tenth of the sample used in the conventional liquids probe.

Modern MAS probes designed for combinatorial analysis are sensitive enough to allow \(^{1}H\)-MAS NMR spectra to be obtained on single resin beads. The \(^{1}H\)-MAS NMR spectra from the stepwise SPS of a hydantoin precursor are shown in Figure 18.\textsuperscript{(130)} Sample preparation involved swelling a single macro bead in DMSO-\(d_6\) and placing it in a Bruker MAS probe. The spectra were generated within 6–8 min by averaging 128–168 scans. The observed
The quality of the spectra obtained by $^1$H-MAS NMR can be enhanced by applying a small decoupling pulse to the signal prior to data collection (presaturation). In some cases, $^1$H-MAS NMR spectra are complicated by the presence of broad peaks related to the polystyrene matrix of the resin. Garigipati et al. have reported that this type of interference from the resin matrix can be eliminated by application of spin-echo pulse sequences in the $^1$H-MAS NMR experiments.

Stöver and Fréchet demonstrated the superiority of $^{13}$C-MAS NMR over gel-phase $^{13}$C-NMR in the characterization of solvent-swollen polymers. The narrow line widths observed in the MAS spectra were attributed to the cancellation of residual motional anisotropy within the polymer network. The first application of $^{13}$C-MAS NMR to combinatorial chemistry involved the structural characterization of norborane-2-carboxylic acid epimers attached to a polystyrene resin. The $^{13}$C-MAS NMR spectrum of the resin yielded sharp signals for all of the carbons in the norbornyl system, with an average resolution of 13 Hz. Remarkably, the ratio of peak intensities in the $^{13}$C-MAS NMR spectrum suggested a 60:40 $\text{exo/endo}$ ratio of epimers on the resin, whereas the ratio of epimers in nonbound norborane-2-carboxylic acid is 70:30.

Macdonald et al. applied $^{31}$P MAS NMR to the characterization of oligonucleotides covalently bound to controlled porous glass beads. Changes in the oxidation state of the phosphorus atom and the addition or removal of protecting groups were readily apparent from the shifts in the resonances observed in the $^{31}$P MAS NMR spectra. However, the spectra of many of the oligonucleotides consisted of isotropic $^{31}$P resonances. Thus, $^{31}$P MAS NMR cannot distinguish between di- and trinucleotides, or between linear and branched trinucleotides immobilized on controlled porous glass beads.

The high quality of MAS NMR spectra allows the same types of two-dimensional (2-D) NMR experiments that are performed to assess the structure of compounds in solution to be carried out on solid-phase supports. The first total structural assignment of a resin-bound compound by NMR was reported in 1995. Heteronuclear multiple quantum coherence (HMQC) spectroscopy and total correlation spectroscopy (TOCSY) MAS NMR spectra for Wang-bound Fmoc-lysine-$t$-butoxycarbonyl (Boc) (see Figure 19) enabled complete assignment of the aliphatic resonances in the compound.

While the line widths in $^1$H-MAS NMR spectra are sufficiently narrow to distinguish between protons based on chemical shift information, they are too broad to reveal couplings. Shapiro et al. have reported that coupling information can be obtained from resin-bound compounds by performing 2-D $J$-resolved NMR experiments. Spin-echo correlated spectroscopy (SECSY) can
Figure 18 $^1$H-MAS NMR spectra of a suspension of individual resin particles in the hydantoin reaction sequence: spectra of (a) the support-bound polyoxyethylene spacer, (b) with acid-labile linker, (c) after treatment with 9-fluorenylmethyloxycarbonyl (Fmoc) phenylalanine, and (d) after scission of the Fmoc group and treatment with isocyanate. (Reproduced by permission of Wiley-VCH from M. Pursch, G. Schlotterbeck, L.H. Tseng, K. Albert, W. Rapp, Angew. Chem. Int. Ed. Engl., 35, 2867–2869 (1996).)
simultaneously provide spin connectivity and coupling information\(^{(139)}\) for protons in resin-bound molecules. SECSY data contains the same connectivity information provided by homonuclear shift correlation spectroscopy (COSY), but retains the enhanced resolution of 2-D \(J\)-resolved experiments.

Nuclear Overhauser effect (NOE) spectroscopy is routinely applied to characterize the three-dimensional (3-D) structure of peptides and proteins in solution. Several research groups have used NOE analysis to determine the secondary structure of resin-bound peptides.\(^{(140,141)}\)

5.2 Off-resin Analysis by Nuclear Magnetic Resonance Spectroscopy

Despite the strengths of NMR as a powerful spectroscopic method, it is difficult when using most NMR techniques to distinguish between a compound of interest and any impurities or contaminants that may be present in the sample. Structure elucidation of mixtures of unknown organic compounds with overlapping \(^1\)H-NMR signals is difficult, especially in spectral regions that are crowded with many resonances. What is needed for the NMR analysis of combinatorial libraries is a means of distinguishing between the individual sample components during spectral acquisition. Flow-through interfaces have been developed to directly couple HPLC and NMR, and this allows individual components present in a sample to be spatially resolved prior to their characterization by NMR. A second approach distinguishes between individual components of a sample solution based on differences in their diffusion rates, and does not require a separation step to be performed prior to NMR analysis.

5.2.1 Flow-through Nuclear Magnetic Resonance Interfaces

The first flow-through interfaces for liquid chromatography/nuclear magnetic resonance (LC/NMR) were developed in the late 1970s.\(^{(142,143)}\) However, the NMR spectrometers used in these systems employed iron magnets with low field strengths, so sensitivity was severely limited (e.g. 100-\(\mu\)g detection limit). Developments during the early 1980s\(^{(144-146)}\) led to the first applications of on-line LC/NMR employing superconducting magnets. Flow-through interfaces for LC/NMR consist of a hollow glass tube, through which the LC eluant flows, and an RF coil wrapped around the outside of the detection window. The design of the RF coil and related circuitry, and the internal volume and geometry of the flow cell differ by manufacturer. Diagrams of a Bruker (Karlsruhe, Germany) continuous-flow NMR probe and typical LC/NMR system configuration are shown in Figure 20.\(^{(147)}\) The Bruker flow cell is a
COMBINATORIAL CHEMISTRY LIBRARIES, ANALYSIS OF

U-shaped glass tube with a slight bulge at the detection window. An RF coil is attached to the outside of the glass tube at the bulge. The LC/NMR probe is preceded by a switching valve (see Figure 20b) that allows spectra to be collected in either continuous-flow or stopped-flow mode. The latter allows NMR experiments involving the collection of hundreds to thousands of transients to be performed without interrupting the LC separation.

In contrast to conventional NMR liquids probes, which typically spin the sample at 20 Hz to expose the sample to a uniform magnetic field, the continuous-flow probes used in LC/NMR are static. As a consequence, the NMR line widths observed in LC/NMR are 3–4 times greater than those in conventional NMR spectra. Continuous-flow LC/NMR probes produce additional line broadening when used in on-flow rather than stopped-flow mode, because the observed nuclei have limited residence times within the detection region of the probe compared with their spin–lattice and spin–spin relaxation times. Dorn reported that a sample should be resident in the detection region of a LC/NMR flow cell for a minimum of 1–6 s to minimize line broadening. (144)

The volume of sample within the region of the RF coil of a continuous-flow LC/NMR probe is only slightly smaller than the total volume of the glass cylinder containing the detection area. This high filling factor helps offset the negative effects of failing to spin the LC/NMR cell within the magnetic field. The detection limits that can be achieved with ¹H-NMR continuous-flow probes are dependent on the number of equivalent nuclei within the detection coil, and the spin–lattice relaxation ($T_1$) times of the observed protons. Albert(147) reported a detection limit of 500 ng for the benzyl CH$_2$ protons of n-butylbenzylphthalate obtained with a flow cell with a volume of 120 µL on a 600-MHz instrument. Detection under stopped-flow conditions is approximately an order of magnitude more sensitive than in on-flow mode, because of the improvements in the signal-to-noise ratio that can be achieved with long acquisition times.

Miniaturization of the basic flow-through cell design has been described for microcolumn and nanoscale separation techniques (e.g. capillary zone electrophoresis, capillary electrochromatography, and capillary HPLC). (148–150)

5.2.2 Liquid Chromatography/Nuclear Magnetic Resonance

LC/NMR has been applied extensively in drug metabolism studies in the pharmaceutical industry. (151–155) The relative ease with which information-rich spectra can be obtained using this technique has enabled the rapid identification of important drug metabolites in a variety of complex matrices, including blood, urine, tissue, and bile. There have been comparatively fewer applications of LC/NMR to combinatorial chemistry, presumably because commercial systems have only recently been developed for combinatorial chemistry and software for data reduction of libraries of compounds is not widely available. Chin et al. (156) reported the analysis of a mixture of four isomeric (dimethoxybenzoyl)glycines by high-performance liquid chromatography/nuclear magnetic resonance (HPLC/NMR) in 1998. The isomers were separated by reversed-phase HPLC, and NMR spectra were generated using both on-flow and stopped-flow conditions on a 500-MHz instrument. A UV chromatogram of the sample mixture is shown in Figure 21(a), and the ¹H-NMR spectra of the four components present are shown in Figure 21(b).
Figure 21 (a) UV trace of the chromatographic separation for a mixture of four isomeric (dimethoxybenzoyl)glycines and (b) their corresponding 500 MHz ¹H-NMR spectra. (Reproduced with permission from J. Chin, J.B. Fel, M. Jarosinski, M.J. Shapiro, J.R. Wareing, J. Org. Chem., 63, 386–390 (1998). Copyright 1998 American Chemical Society.)
Suppression of signals from the chromatographic eluent is a critical challenge to LC/NMR. There are a number of techniques available for eliminating interference from proton-containing solvents in LC/NMR systems. The most direct approach to eluent signal suppression involves using deuterated or halogenated solvents in the LC mobile phase. However, the high cost of deuterated solvents makes this approach impractical for conventional reversed-phase applications. Electronic pulse techniques provide the best approach to solvent signal suppression in LC/NMR. Presaturation to suppress interfering solvent signals requires lengthy saturation periods during which sample spectra cannot be acquired, which limits application of this technique to stopped-flow analysis.\(^\text{157}\) Binomial suppression methods, such as the 1–1 hard pulse and 1331 pulse sequences\(^\text{158,159}\) are compatible with on-flow analysis and can be used to suppress multiple solvent resonances simultaneously. Pulsed-field gradients also provide a useful means of suppressing background water signals in one-dimensional (1-D) and 2-D NMR experiments.\(^\text{160–162}\) Developments in solvent suppression techniques for LC/NMR have been reviewed.\(^\text{163}\)

5.2.3 Diffusion-resolved Nuclear Magnetic Resonance

Morris and Johnson\(^\text{164,165}\) developed a 2-D NMR technique that allows \(^1\)H-NMR spectra of discrete chemical species present in mixtures to be distinguished based on differences in their diffusion coefficients. 2-D NMR diffusion-ordered spectroscopy (DOSY) is performed in two steps. The first step of the DOSY experiment involves generating the 2-D NMR data using pulsed-field-gradient NMR techniques. The data are subsequently transformed and displayed with chemical shift information plotted in one dimension and diffusion coefficients in the second dimension. Transformation of NMR signal intensities versus gradient pulse areas into diffusion spectra is performed using standard computer algorithms. DOSY is potentially a powerful technique for characterizing mixtures of low-molecular-weight compounds of similar size, such as those present in combinatorial mixture libraries. A significant advantage of DOSY over LC/NMR is that spectra on individual compounds present in a mixture can be obtained directly, without requiring an initial chromatographic separation.

Extension of the standard DOSY experiment to include \(^13\)C correlation information as a third dimension has been reported by Barjat et al.\(^\text{166}\) The 3-D diffusion-ordered spectroscopy/heteronuclear multiple quantum coherence (DOSY/HMQC) spectrum of a mixture of quinine, camphene, and geraniol in methanol-\(d_4\) is shown in Figure 22.\(^\text{166}\) Lin et al.\(^\text{167,168}\) combined pulsed field gradients with TOCSY in a technique they termed diffusion-encoded spectroscopy (DECODES). A limitation of DOSY is that overlapped resonances in the region between 0.5 and 2.0 ppm cannot always be resolved by diffusion alone. TOCSY, however, can resolve overlapped resonances by separating coupled spin systems in the second dimension. Hence, the DECODES technique is more effective in resolving individual components present in complex mixtures.

6 LIBRARY SCREENING BY AFFINITY SELECTION AND MASS SPECTROMETRY

Classical approaches to drug discovery involve synthesizing, purifying, characterizing and biologically screening compounds one at a time. While there have been significant advances in methods for synthesizing large numbers of compounds in combinatorial libraries, there are relatively few techniques available for screening mixtures of compounds in ways that allow detection of specific receptor–ligand interactions and preserve the native binding of these interactions. Most screening approaches use classical bioassays to test the activity of single compounds, but perform these assays in parallel to increase sample throughput (i.e. high throughput screening). Affinity-based assays, while compatible with mixtures of ligands, employ immobilized receptors or immobilized ligands and yield binding constants that may not mimic true solution-phase binding.

During the mid-1990s, a number of affinity-based screening techniques were developed to overcome the disadvantages of conventional assays. These improved strategies combine the high specificity of mass spectrometric detection with novel approaches for distinguishing receptor-bound ligands from unbound species present in combinatorial mixture libraries.
6.1 Ligand Selection by Affinity Chromatography

Affinity chromatography is a technique wherein a mixture of ligands is chromatographically separated based on their interaction with an immobilized receptor. The target receptor usually is immobilized on a solid support, and packed into a column. A solution containing the mixture library is passed through the column, and those compounds that interact strongly with the receptor are fully retained. Compounds that interact weakly with the immobilized receptor, or not at all, pass through the column unretained. The strongly retained compounds then are eluted from the affinity column using a high-ionic-strength buffer. The active mixture is passed through a desalting column to remove buffer salts, and individual components in the mixture are separated by reversed-phase HPLC prior to their characterization by ESIMS. A disadvantage of affinity chromatography as a compound selection technique is that the immobilization of receptors to the solid support may alter their binding with ligand molecules.

A variety of approaches to library screening by affinity selection and MS have been described, and they all utilize affinity separation for compound selection and ESIMS for compound identification. Nedved et al. developed an automated system for screening benzodiazepine combinatorial libraries. This system consists of an immunoaffinity column containing antibodies to benzodiazepines and two reversed-phase HPLC columns coupled to a triple-quadrupole mass spectrometer through a series of electronic switching valves (see Figure 23). A mixture of benzodiazepines is passed through the immunoaffinity column, where active compounds bind to the immobilized antibodies. A pH step-gradient is used to release the benzodiazepine–antibody complexes from the immunoaffinity column onto a restricted access media stationary phase that separates the active benzodiazepines from the antibody. A C-8 reversed-phase column is then used to separate the mixture of active benzodiazepines before they enter the mass spectrometer. Kelly et al. adopted a more conventional approach to identify peptides that bind strongly to the Src homology 2 (SH2) domain of phosphatidylinositol 3-kinase. Active peptides eluted from a SH2 affinity column were desalted on a small molecule trap column prior to their characterization by ESIMS.

Karger et al. developed an approach to library screening based on affinity capillary electrophoresis and mass spectrometry (ACE/MS). In affinity capillary electrophoresis (ACE), the electrophoretic mobility of a ligand in solution is altered upon complexation with a receptor molecule. Complexation with the receptor shifts the mobility of the ligand to that of the complex, and this shift in mobility corresponds to the ligand’s binding affinity to the receptor. In the ACE/MS experiment, the capillary is filled with a running buffer containing the receptor. A mixture of ligands is injected into the inlet side of the capillary prior to the start of electrophoresis. Ligand molecules (both bound and free) are introduced into the electrospray source of the mass spectrometer as they migrate past the capillary exit. An advantage of ACE/MS is that the compound selection and compound identification steps of the library screening process are combined into a single step. The ACE/MS technique has been applied successfully to the screening of peptide libraries, but the technique may not be applicable to libraries of small-molecule organic compounds due to the complexities involved in developing electrophoretic separation conditions appropriate for these types of compounds.

6.2 Ligand Selection by Gel-filtration

Gel-filtration columns are packed with hydrophilic polymer beads of controlled porosity. These columns separate compounds primarily on the basis of molecular size and shape. Large molecules are excluded from the interior porous region of the beads and elute at or near the void volume of the column. Small molecules travel deep within the interior of the beads and take longer to elute from the column. The use of gel-filtration columns in library screening has focused primarily on the separation of receptor-bound ligands from combinatorial mixture libraries. Typically, a solution containing compounds from the mixture library is incubated with a solution containing the target receptor. The mixture then is passed through a gel-filtration column, where the bound ligands elute with the receptor molecules, while the unbound ligands are retained for longer. The receptor-bound ligands are liberated from the target and characterized by LC/ESIMS. A variant of this procedure has been incorporated into an automated screening methodology termed Selectronics™ and is illustrated in Figure 24. In addition, this general screening procedure has been used in competitive binding experiments to identify library components with optimum binding affinity.

Gel-filtration separations are best suited to ligands that have high affinity for the receptor molecule (Kd < 1 μM). Loss of ligand during the gel-filtration step is possible if the rate of dissociation of the receptor–ligand complex is fast compared with the separation time. In addition, irreversible retention of the receptor on the gel-filtration support can lead to poor ligand recoveries.

6.3 Ligand Selection by Ultrafiltration

Ultrafiltration membranes are a convenient and more robust alternative to gel-filtration columns for separating
Figure 23 Characterization of benzodiazepine combinatorial libraries by on-line immunoaffinity extraction coupled with HPLC–ion spray MS. Valve positions for (a) loading antibody and chemical library onto the immunoaffinity extraction (IAE) column, (b) desorbing benzodiazepine–antibody complexes onto the trap column (TC), and (c) backflushing the trap column on to the analytical reversed-phase column. (Reproduced with permission from M.L. Nedved, S. Habibi-Goudarzi, B. Ganem, J.D. Henion, *Anal. Chem.*, 68(23), 4228–4236 (1996). Copyright 1996 American Chemical Society.)
molecules on the basis of size. Ultrafiltration membranes are manufactured of microporous cellulose triacetate or polysulfone in a variety of molecular weight cutoffs. The nominal molecular weight cutoff of an ultrafiltration membrane refers to the molecular weight of a globular protein that is 90% rejected by the membrane. Compounds with molecular weights significantly below the molecular weight cutoff pass freely through the membrane. Due to their relatively smaller surface areas, sample losses related to irreversible adsorption are rarely observed with these devices.

Van Breemen et al. developed the technique of pulsed ultrafiltration MS by combining on-line ultrafiltration with electrospray MS. Pulsed ultrafiltration MS allows the rapid screening of combinatorial libraries for ligands that bind to receptors in solution. An outline of this technique is shown in Figure 25. The technique employs a flow-through chamber consisting of two compartments separated by an ultrafiltration membrane. During pulsed ultrafiltration, receptor-bound ligands remain in one half of the ultrafiltration chamber, while unbound compounds pass through the membrane and are washed away. Release of bound ligands is achieved by adding a small aliquot of an organic solvent to the sample compartment. The released compounds are then continuously monitored by ESIMS. The pulsed ultrafiltration chamber design allows the receptor to be reused for subsequent binding experiments, and is compatible with competitive binding studies and detection of strong-affinity ligands present at dilute concentrations in the presence of higher concentrations of weaker binders. For example, the adenosine deaminase inhibitor, erythro-9-(2-hydroxy-3-nonyl)adenine, was readily detected from a mixture of 20 adenosine analogs despite being present at a 10-fold lower concentration than the other ligands.

Wieboldt et al. employed ultrafiltration membranes to screen mixtures of benzodiazepines for binding affinity to antibodies raised to nitrazepam, temazepam, and oxazepam. Benzodiazepine mixtures were incubated with a specific antibody in 10 mM ammonium acetate buffer at pH 5.0, and the unbound drug ligands were separated by centrifugal filtration through a 50 000 molecular weight cutoff ultrafiltration membrane. The bound ligands were

characterized by HPLC and ESIMS, following their release from the antibody–drug complex by treatment with 1% TFA in water.

### 6.4 Bio-affinity Characterization Mass Spectrometry

All of the approaches to library screening described so far treat affinity selection and identification of active compounds as separate steps. As a result, these techniques have limited sensitivity due to the loss of ligand introduced by the additional sample handling required. An alternative approach developed by Smith et al. eliminates the need for distinct separation and purification steps prior to ESIMS characterization. Bio-affinity characterization mass spectrometry (BACMS) combines ESI with Fourier transform ion cyclotron resonance (FTICR) MS in a technique that enables the direct characterization of noncovalent receptor–ligand complexes formed in solution. The basic BACMS experiment is depicted in Figure 26. A solution containing the affinity receptor and ligand library is infused into the electrospray source, where the individual species and receptor–ligand complexes are transferred into the gas phase. These gas phase ions are trapped in the FTICR chamber, and the receptor–ligand complexes of interest are isolated by selected-ion accumulation. The selected-ion accumulation process is sufficiently gentle to prevent dissociation of the noncovalent complexes and allows these complexes to be observed with a good signal-to-noise ratio. This accumulation step is immediately followed by low-energy dissociation, which isolates the selected ligand molecules in the FTICR chamber. Collisionally activated dissociation then may be performed to obtain structural information on the high binding affinity ligands.

BACMS has been used to screen 256–289 member tripeptide libraries for tight binding inhibitors to carbonic anhydrase II obtained from bovine erythrocytes. In this work, the relative intensities of the ions dissociated from the carbonic anhydrase II–inhibitor complexes correlate well with the binding constants of these inhibitors in solution (see Figure 27). This correlation between solution-phase and vapor-phase ordering of binding constants suggests that the data from BACMS experiments may be used to predict the order of binding affinities in solution.

Higger et al. monitored the reaction between 1-chloro-2,4-dinitrobenzene (CDNB) and components of a H–γ–Glu–Cys–Xxx–OH (where Xxx is any natural amino acid except Cys, Val, Thr, and Pro) tripeptide library catalyzed by the enzyme glutathione-S-transferase (GST). Assessment of GST substrate specificity relied on detection of the products formed by reaction of the tripeptide library with CDNB, rather than on identification of tight binding ligands to the enzyme. In addition, the presence of two substrate-binding pockets on the

![Figure 27](image)

GST enzyme allows optimization of substrate specificity to be extended to two dimensions. Two substrate libraries each targeting one of the two binding sites on the GST enzyme would result in the formation of products representing the best binding substrates from each library.

7 COMBINATORIAL LIBRARY QUANTITATION

Classical methods for handling compounds in a traditional drug discovery environment require large quantities (0.1–1.0 g) of highly pure material. Product yields from organic synthesis usually are calculated based on the mass of purified product obtained. Accurate measurement of pharmacological activity requires that known concentrations of test compounds be prepared by dissolving an accurately weighed amount of compound in an accurately measured volume of solvent. Product yields from combinatorial library synthesis often are too low (1–10 mg) to permit accurate weighing. In addition, split-synthesis techniques produce mixtures that are difficult to quantitate on a per-compound basis. Consequently, there has been considerable interest in developing reliable methods for determining the reaction yields and solution concentrations of combinatorial samples that do not require individual compounds to be accurately weighed.

The combination of HPLC and UV detection provides a rapid, reproducible, and sensitive means of quantifying compounds in solution. Accurate quantitation by UV, however, requires the use of well-characterized reference standards due to the wide variability in the molar absorptivity of organic compounds, and this has presented a serious impediment to the quantitation of combinatorial samples. Accurate quantitation of combinatorial samples requires a detector whose response depends only on the amount (concentration) of compound present in solution and provides a signal that is independent of molecular structure. Three detectors have emerged that are compatible with the requirements of HPLC and provide the degree of “universal” response required for accurate quantitation of combinatorial samples.

7.1 Quantitation using 1H-Nuclear Magnetic Resonance Spectroscopy

Sample quantitation by 1H-NMR is superior to quantitation by UV detection, because the integral intensity of a given resonance band in a 1H-NMR spectrum is directly proportional to the number of proton nuclei contributing to that signal. Optimizing the instrument parameters to minimize quantitation errors, however, requires an understanding of the processes involved in acquiring a spectrum. During an NMR experiment, the bulk magnetization of protons in the analyte molecule is perturbed through application of an RF pulse. After a short delay, the exponential free induction decay (FID) signal produced as the system returns to equilibrium is digitized, averaged, and transformed to yield a frequency domain spectrum. The exponential decay of the FID signal is a function of the spin–spin ($T_2$) relaxation time, while return of the perturbed spin system to equilibrium is governed by the spin–lattice ($T_1$) relaxation time. In other words, the acquisition time in an NMR experiment depends on $T_2$, while the pulse repetition rate depends on $T_1$. The value of $T_1$ usually is greater than $T_2$ for organic molecules with a molecular weight less than 1000 Da.

A significant problem in obtaining accurate quantitation in 1H-NMR is related to variable spin–lattice relaxation times among protons in the sample molecule. Quantitation errors arise when the RF pulse rate is faster than $T_1$ for any of the sample nuclei. The situation becomes more complex when sample quantitation is performed using flow-through NMR systems. The effective $T_1$ and $T_2$ values of a proton in a flow-through system are related to their static values and the residence time of the molecule in the NMR detector coil. As a consequence, quantitative NMR experiments should be designed such that the RF pulse rate is five times the value of $T_1$ for the proton with the longest spin–lattice relaxation time, and the sample is resident within the region of the NMR detector coil for 1–6 s during measurement. A number of additional experimental factors that can lead to spectral distortions in NMR and interfere with sample quantitation have been described.

Quantitation by 1H-NMR spectroscopy involves measuring the integral intensity of a specific sample resonance band relative to that of a resonance band corresponding to an internal standard. The major requirements placed on the choice of internal standard are: the proton resonances of the internal standard should not overlap the resonances from the sample; the internal standard must be chemically compatible with the sample; and the nuclei in the internal standard should have short $T_1$ relaxation times. Hexamethyldisiloxane is a useful internal standard for 1H-NMR, because of its small chemical shift (0.07 ppm) relative to tetramethylsilane. In a conventional quantitation experiment, the sample and internal standard are combined in a standard NMR sample tube, and a 1H-NMR spectrum recorded in the usual manner. The concentration of sample in solution is calculated as shown in Equation (1):

$$M_a = \frac{I_s n_s M_s}{n_a I_s}$$

(1)
where \( n \) represents the number of protons assigned to the resonance signal, \( M \) is the molar concentration, and \( I \) is the integrated intensity of the internal standard (s) and analyte (a). This method will lead to erroneous quantification results if the sample contains impurities with \(^1\)H-NMR resonances that overlap the signals corresponding to the compound of interest. Accurate quantitation of mixtures is achieved by performing a chromatographic separation prior to \(^1\)H-NMR analysis.

The requirements for sample quantitation in continuous-flow HPLC/NMR experiments have been elaborated by Godejohann et al.\(^{187}\). There are two methods for incorporating an internal standard in an HPLC/NMR experiment: direct addition of the internal standard to the HPLC mobile phase; and injection of a fixed amount of internal standard following sample injection. The former technique is employed in gradient HPLC to compensate for the influence of varying eluent composition on the intensity of resonance bands in the NMR spectrum. Injection of a fixed volume of the internal standard following sample injection is compatible with isocratic HPLC separations.

The technique of sample quantitation by \(^1\)H-NMR with internal standard has been applied successfully to the determination of the potency of active ingredients in pharmaceutical dosage forms\(^{188}\) and the yield of products originating from the SPS of combinatorial libraries.\(^{189}\) A representative \(^1\)H-NMR spectrum of a product from a combinatorial library in the presence of internal standard is shown in Figure 28.

7.2 Quantitation using Chemiluminescent Nitrogen Detection

Chemiluminescent nitrogen detection (CLND) instruments respond only to nitrogen present in organic compounds. Sample detection by CLND involves oxidizing the sample at approximately 1000 °C to convert nitrogen in the compound to nitric oxide. The nitric oxide is reacted with ozone to produce nitrogen dioxide in an excited state, which releases a photon as it returns to the ground electronic state. The emitted photons are detected using a photomultiplier tube, whose output is amplified to yield an analog signal. In contrast to UV detectors, the response of a chemiluminescent nitrogen detector is linearly related to the total mass of compound present in the sample and is independent of concentration.

The first practical application of CLND coupled with HPLC was reported by Fujinari et al.\textsuperscript{190} for the analysis of ammonium nitrogen in wastewater. The combination of reversed-phase HPLC and CLND has been applied successfully to the purity assessment of synthetic peptides.\textsuperscript{191} This combination of a high resolution separation technique and “universal” detection also has been utilized to assess product yields and purities of nonpeptide combinatorial libraries.\textsuperscript{192,193} A series of chromatograms comparing the response of an equimolar mixture of nitrogen-containing organic compounds separated by gradient reversed-phase HPLC with UV detection at 214 nm and 270 nm and CLND is shown in Figure 29.

CLND has been reported to yield similar response to nitrogen-containing, small-molecule organic compounds over a linear range of 25 to 6400 pmol of nitrogen.\textsuperscript{195} Furthermore, quantitation by CLND results in an error of approximately 10% over a wide range of compound classes. The use of CLND as a detector in reversed-phase HPLC imposes practical limitations on the choice of mobile phase eluents and buffers. Mobile phase components must be nitrogen-free, hence organic alcohols (e.g. methanol) are frequently used in place of acetonitrile as mobile phase modifiers.

7.3 Quantitation using Evaporative Light Scattering Detection

Like CLND, evaporative light scattering (ELS) detectors respond to the total mass of compound injected, rather than yielding a concentration-dependent response. The principle of operation of an ELS detector is based on measurement of the intensity of light scattered by the analyte following evaporation of the carrier solvent (e.g. the HPLC mobile phase). The HPLC column effluent enters the detector through a narrow bore tube where it is mixed with a high-velocity stream of nitrogen gas and passed through a nebulizer. The nebulized sample stream enters a heated tube, maintained at a sufficient temperature to cause rapid evaporation of the carrier solvent. The stream of solid analyte particles that is produced passes a detection system consisting of a source and photodiode detector placed 90° apart and perpendicular to the central axis of the drift tube. As the analyte passes through the detection region, the solid particles scatter light through a combination of Mie-scattering, reflection and refraction.\textsuperscript{194,195} The intensity of the scattered light is measured by the photodiode and amplified to produce an analog signal proportional to the

![Figure 29](image_url) Chromatograms of a mixture of ‘drug-like’ compounds separated by reversed-phase HPLC with gradient elution and detected by UV at 214 nm and 270 nm and by CLND. The injected sample contained 2 nmol each of (1) caffeine, (2) triprolidine, (3) chlorpheniramine, (4) diphenylalamine, (5) 6-nor-6-allylsergic acid diethylamide, (6) angiotensin II, (7) diphenhydramine, (8) doxepin, and (9) dibucaine. (Reproduced with permission from E.W. Taylor, M.G. Qian, G.D. Dollinger, \textit{Anal. Chem.}, \textbf{70}, 3339–3347 (1998). Copyright 1998 American Chemical Society.)
amount of analyte present in the injected sample. ELS detectors exhibit a sigmoidal response to compounds, but, the detector’s response can be made linear over a range of 2–3 orders of magnitude by plotting intensity versus mass on a log/log scale. The ELS detector’s nonlinear response is attributed to the physics of Mie-scattering. The Mie-scattering efficiency of particles is maximal over a narrow range of particle diameters. Small radius particles generated at low analyte concentrations scatter less efficiently, while at high analyte concentrations changes in the surface-to-volume ratio of larger radius particles leads to less efficient light-scattering.

When combined with HPLC instruments, ELS detectors are highly effective at providing on-line quantitation of small organic compounds derived from combinatorial libraries. Reliable quantitation requires that a well-characterized standard belonging to the same class of compounds present in the combinatorial library be used to calibrate the detector. The pair of chromatograms shown in Figure 30 illustrate the more “universal” response of ELS detection compared with conventional UV detection towards compounds of similar structural class (e.g. steroids). The response of the ELS detector depends on the ability of the nebulizer to produce analyte particles of the optimal size (0.8 µm) for effective Mie-scattering. This process is dependent on a variety of factors including solvent vaporization enthalpy, nebulizer gas flow rate, solvent composition, analyte molecular weight, and analyte polarity. The best results are obtained with HPLC separations performed under normal-phase conditions with solutes of a mass greater than 150–200 Dal.

High-performance liquid chromatography (HPLC) is one of several separation techniques that are based on the differential migration of an analyte (solute) through a fixed medium as the result of a driving force, the eluent. In the case of HPLC, the eluent is typically either a binary or ternary mixture of solvents and the stationary phase is most often a porous adsorbent or a chemically bonded phase attached to a porous substrate. The rate of migration of an individual solute and the separation between groups of solutes are governed by their interactions with the stationary phase. Thus, the optimization of an HPLC method involves the selection/adjustment of the physical and chemical parameters which control the rate of migration of the solute in such a fashion that baseline resolution is obtained between it and other co-analystes or interfering compounds within the mixture. In doing this, given a series of closely related compounds, it is important to identify structural differences between solutes and to maximize the interactions with the stationary phase arising from them. This article considers the important physical and chemical aspects of the solute, eluent, and stationary phase in terms of chemical equilibria, solute structure, eluent conditions, operational parameters, and nonideal effects. Likewise, as several approaches may lead to acceptable analytical separations, other performance criteria such as simplicity, reliability, speed, and cost also are discussed in terms of arriving at the optimal method.

1 INTRODUCTION

Since the late 1960s HPLC-based methods have become increasingly popular in the analysis of pharmaceuticals and currently are the most widely used procedures. Their growing acceptance has resulted from the inherent versatility and reliability of the methodology, as well as from improvements in hardware performance and ease of automation of the procedures. Likewise, fundamental sample considerations such as thermal instability, low volatility, and matrix complexity have been important contributing factors in their increasing use.

1.1 Understanding the Problem or Sample

In developing appropriate cost-effective HPLC methods, as with analytical procedures in general, it is important to consider the total problem to be solved. This not only includes the development and optimization of a method in terms of analyte and matrix considerations, separation and detection design, and validation, but it also should take into account the end-usage and user skills. Often, these latter aspects may be the overriding factors in determining the final assay design. If the intended application of a new procedure is as a routine high-throughput assay for assuring that a single active ingredient is within acceptable levels during manufacture of the formulated product, then simplicity, reliability, speed, and cost become important factors in selecting the overall methodology.

What is eloquent in the research and development laboratory may be too complex, expensive, and unreliable for the quality assurance setting. Often simple isocratic approaches are more effective than gradient elution procedures and methods that are based on them are easier to carry out by the less trained practitioner. Similarly, ease of use and reliability are two important considerations in choosing a given approach such as the use of reversed phase (RP) conditions over normal phase...
assay a variety of compounds ranging from simple tablet analysis liquid chromatography (RALC) has been used to and more problematic compounds such as alkaloids, 

... tion and poorly formed or varying peak shapes, result their method. Many of the problems associated with assay considerations or choose to ignore relatively simple fundamental a given separation, but they sometimes either fail to con- sider how to systematically change conditions in order to effect an effective separation. Columns for RA, which are available from a number of manufactures, are typically 30–50 mm in length and are packed with 2–5 µm porous materials. However, columns packed with nonporous particles have been developed recently as alternative media for carrying out highly efficient fast separations. Rapid analysis liquid chromatography (RALK) has been used to assay a variety of compounds ranging from simple tablet formulations of acetaminophen to combined products and more problematic compounds such as alkaloids, antibiotics, barbiturates, and hormones.

Alternatively, if the problem to be solved involves more complex samples or less routine usage such as that encountered during the discovery and development stages of a drug, then specificity, versatility, and flexibility are the more important factors. Some typical examples of these are encountered in: (1) the development of a reference standard material, (2) evaluating the purity of the drug substance, (3) stability testing of the active ingredient and its various formulations, and (4) measurements of bioavailability and pharmacokinetics. In many cases gradient and multilevel elution approaches and combination column assays may not only be more convenient but necessary, in order to resolve a mixture of compounds produced via a complex synthetic route or if the target compound is a natural product or is produced via a fermentation process. Additionally, gradient elution approaches may provide an important advantage in the detection of trace impurities, especially if they vary significantly in their structures and polarity.

Generally, most practising chromatographers understand how to make their hardware work effectively, and they have a reasonable empirical/working knowledge of how to systematically change conditions in order to effect a given separation, but they sometimes either fail to consider or choose to ignore relatively simple fundamental concepts that influence the reliability and ruggedness of their method. Many of the problems associated with assay instability, such as erratic or slow changes in solute retention and poorly formed or varying peak shapes, result from poorly designed procedures that may provide the desired resolution but are not optimized to minimize variability. Thus, this article addresses the topic of optimization, pointing out whenever possible strategies that improve performance, especially when the assay is to be transferred from a research setting to the quality assurance laboratory and used routinely to monitor production runs.

1.2 Important Physical and Chemical Aspects of the Analyte

Besides the general sample/problem considerations noted above, a fundamental understanding of the physical and chemical aspects of the analyte are important in the systematic design of a reliable method. The first question that should always be asked in adopting an HPLC strategy should be “is a liquid chromatographic approach the best solution?” If the sample is thermally stable and volatile, then the answer for most analytes is no. For these types of analytes, methods based on gas chromatography are likely better approaches in terms of cost, simplicity, and reliability. However, if volatility and thermal stability are concerns, then liquid chromatography has been and continues to be the preferred approach in a majority of cases. A working knowledge of the analyte’s solubility in different solvents and its molecular properties in terms of size, structure, and equilibrium characteristics is important in selecting the overall separation and detection approaches, in choosing the column and eluent, and if necessary in fine-tuning the method in terms of the secondary modifiers needed. Likewise, an understanding of the possible contaminants and by-products that may arise during the chemical synthesis or isolation steps and of degradation products that may be formed as the result of drug instability or drug excipient and package interactions are important in validating assay specificity.

In the general design of a separation, given a series of closely related analytes, it is important to identify that portion of the solute which contains the structural differences and to enhance their interactions with the stationary phase. In some cases these are easily recognized; however, with increasing molecular complexity or with structurally dissimilar compounds, the problem becomes more difficult. As the approaches most often used in pharmaceutical analysis generally involve some form of RP separation, an important item of additional information is the protonation and deprotonation characteristics of the analyte. Although there may be a number of reversed-phase liquid chromatography (RPLC) conditions that will produce a satisfactory separation, some are preferable based on assay ruggedness, cost, and ease of use. It cannot be over emphasized that many of the commonly encountered
problems are associated with the solute and the stationary phase in terms of simple equilibrium considerations. Examples of these types of problems are fluctuations in the retention factor, \(k^0\), and poorly formed peaks when RP separations are carried out at or near a solute’s \(pK_a\), and significant peak tailing for solutes which interact strongly with residual silanols. The logical selection of eluent additives, such as buffers, ion-pairing compounds, and masking reagents, requires a general understanding of the equilibria that govern the solute and its interactions with the stationary phase as well as knowledge about the nonideal nature of the stationary phase and residual silanol activity.

Shown in Figure 1 is the RP separation of a series of important pharmaceutical additives carried out using a conventional short (4.6 mm internal diameter × 30 mm) octadecyl column. Figure 2(a) is the same separation using identical eluent conditions on a higher-efficiency wide-bore (7.0 mm internal diameter × 30 mm) RA column. In performing this latter separation, the flow rate of the eluent was adjusted to give an equivalent linear flow velocity to that used in Figure 1. The accompanying chromatograms (Figures 2b and c) illustrate how analysis speed can be enhanced by simple increases in flow rate.

Under the RP conditions used in Figures 1 and 2, the differences in retention of the ester homologs of \(p\)-hydroxybenzoic acid are governed by the interactions of the alkyl portion of the compound and the immobilized alkyl chains of the bonded octadecyl phase. The relationship between retention and size (i.e. carbon number) of the aliphatic portion of the paraben homologs is logarithmic, and a plot of \(\ln k^0\) against the carbon number is linear with a slope related to the incremental methylene selectivity. The substitution of a series of \(-CF_2-\) units in place of methylene units also results in similar incremental group additivity. The predictable nature of retention for homologs is illustrated in Figure 3 within a given column and between columns packed with similar stationary phases. Nonionizable homologs, like the parabens, are often useful as internal standards as they cover a range of predictable retention times under various eluent pH conditions, and they have similar detector response.
responses. Similar linear relationships are obtained for other classes of compounds including ionizable solutes by controlling their deprotonation. This topic is discussed in greater detail in section 3.2.

Structural features, such as the addition of a polar group (e.g., a hydroxyl group), decrease the overall hydrophobicity of the solute and hence decrease retention under RP conditions. These same features result in increased retention under NP conditions. This is illustrated by the data shown in Table 1 for the anti-inflammatory drug tolmetin and related compounds. Comparing the retention data (i.e., elution order) of compounds b, c, and f, which differ only by the substituent at the R1 position, the greater interaction of the carboxyl group requires a stronger

table 1 influence of structure on the gradient elution separation of a nonsteroidal anti-inflammatory drug and related compounds under np conditions

eluent (8.6 min into the gradient profile shown in Figure 4) compared to the corresponding methyl and ethyl esters that elute at the initial mobile phase conditions (1.2 and 1.6 min into the gradient). Although not shown, these same three compounds should be easily resolvable under RP conditions but in the reverse order with the
same predictable incremental methylene additivity, as discussed above, once the carboxyl group’s deprotonation is suppressed in the case of the parent acid, tolmetin.

The separation summarized in Table 1 is an example of the resolving power of NP methods for structurally similar compounds containing polar substituents. Although NP methods have become less popular because they are more susceptible to retention variability and column fouling, these types of problems can often be minimized. Approaches for doing this are discussed in greater detail in following sections. Under certain conditions, such as the separation of cis and trans isomers, NP methods may be the best choice.

1.3 Selection of the Separation Mode

The selection of the appropriate separation mode, whether it is based on an RP, NP, ion exchange chromatography (IEC), or size exclusion chromatography (SEC) mechanism, is dependent on the solubility and size of the analyte. In some cases, such as the analysis of common inorganic ions, the choice may be relatively straightforward, the methodology almost turnkey (such as the analysis of cations or anions via ion chromatography (IC)) and the retention predictable. By far the most common application of IC is for measuring inorganic ions and it has been applied to a variety of products including injectable solutions, nutritive liquids, and vitamin formulations. Similarly, the application of size exclusion methods have, to a large extent, been used for molecular weight characterizations and determinations of additivities (e.g. polyethylene glycols and microcrystalline cellulose) or to study the properties of a few individual compounds (e.g. the chemical stability of insulin). More recently SEC usage has been increasing with the emerging interest in the development of novel type pharmaceuticals (e.g. polymeric drugs and biotechnology products from peptides, proteins, and DNA. Some recent examples where it is used include determination of the purity and homogeneity of recombinant hepatitis B virus antigens, the analysis of acidic fibroblast growth factor in viscous formulations, and the purification of plasmid DNA for cancer gene therapy.

Another increasingly important problem is the stereochemical purity of pharmaceuticals, as numerous pharmacologically active agents are chiral and their two enantiomeric forms usually exhibit different physiological properties. Typically, three chromatographic approaches are used to resolve chiral pharmaceuticals:

- the direct resolution of the isomeric pairs using achiral stationary phase with a chiral mobile phase additive;
- the direct resolution of the enantiomers on a chiral stationary phase (CSP).

Of these approaches, the latter has become the most popular because of ease and convenience, as well as availability of a host of CSPs. These can be classified into five major groups: (I) Pirkle-type (donor–acceptor) phases, (II) inclusion (chiral cavity) materials, (III) helical polymers, (IV) ligand exchangers, and (V) immobilized peptides and proteins. In the latter instance, chiral recognition is a natural property of biological molecules, and when they are properly immobilized, either by physical adsorption or by covalent attachment, some if not most of their indigenous binding affinities are preserved. Of the reported separations being carried out, many employ columns with type I and type II packing. Although all of the above approaches and examples are important, further consideration of these topics is beyond the general scope and emphasis of the current article.

Although most small multifunctional-containing analytes can be separated by the use of either RP or NP conditions, RPLC is typically the route of choice, as noted earlier. This tendency has arisen based on practical concerns such as greater column ruggedness and ease of clean-up of RP packings, and operational considerations such as often longer equilibration times and instability of NP packings, even though in many cases the actual ability of NP approaches to resolve target compounds may be better. On a thermodynamic basis the problems associated with NP methods are the result of larger heats of adsorption (ΔH) that are two to three times greater than the corresponding ΔH values for solutes interacting with bonded alkyl phases. In extreme cases, for highly polar and larger molecules that contain many strongly interacting groups such as amine, amide and hydroxyl functionalities, irreversible or nearly irreversible sorption many occur.

Under NP conditions, two of the most commonly encountered problems are erratic fluctuations in retention and slowly drifting retention. In many instances these undesirable effects are due to short-term variations in laboratory temperature and slow column equilibration rates, respectively. In the first instance erratic changes in k' can be minimized through appropriate temperature control of the column and eluent. In general for most RP applications a ±1 °C variation in laboratory temperature (i.e. change in the column temperature) will result in only a small variation in k' (~3%). However, under NP conditions it is not unusual to obtain two to three times this change and under certain conditions even an order of magnitude difference may be observed through significant
polarity changes in the sorbed layer of solvent present on the surface.\(^{(27)}\)

The need for temperature control is especially important when NP separations are carried out on polar surfaces such as silica or alumina when using nonpolar carrier eluents (e.g. hexane and small amounts of a highly polar modifier such as an alcohol). These same types of conditions lead to slowly drifting retention, as the packing material may require hundreds of column volumes of the eluent to pass through it to reach equilibrium. This effect is illustrated in Figure 5(a) for a standard 4.6 mm i.d. \(\times 250\) mm silica column using \(n\)-hexane as the carrier eluent and modifying it with varying amounts of three polar alcohols. The curves were generated assuming a simple single-site titration-type adsorption model, an eluent flow rate of 1.0 mL min\(^{-1}\), and a column containing 4 g of silica with surface area of 500 m\(^2\) g\(^{-1}\) and five silanol groups per 100 Å\(^2\) available as adsorption sites. As it is not uncommon to use small quantities (<1%) of an alcohol modifier to obtain useful \(k'\) values, several hours may be needed for the column to reach equilibrium. The horizontal line in Figure 5(a) shows the time needed for the column to reach equilibrium using 0.5 vol% methanol, ethanol, and propanol (2.3, 3.2, and 4.2 h, respectively). Figure 5(b) illustrates this same effect as a function of three different column sizes. An even worse scenario in terms of long equilibration times occurs when hexane or another nonpolar solvent is used alone, due to the presence of trace amounts of dissolved water. This arises because a completely dry silica surface is significantly more retentive of polar compounds than a surface that is fully hydrated. The equilibration time problem often can be minimized if an adequate separation can be developed using an eluent containing larger quantities of the polar modifier and by more careful control of temperature and surface hydration.

As many pharmaceutically active compounds are water soluble and are relatively small to intermediate in size, in a majority of cases they can be resolved more conveniently using RP methodology. By far, the more common approaches employ alkyl-bonded phases in combination with binary hydro-organic eluents. Further, as a majority of the pharmaceutically active compounds contain ionizable groups, such as carboxyl, amine, and amide functionalities, it is necessary to control the pH of the eluent. In the simplest case, where only a single group or at least similar groups are involved, it is advisable to carry out the separation where the solute exists predominately in its uncharged state. This topic is considered in more detail in section 3.2. Generally, this simple strategy works better for acidic compounds than for bases because of equilibrium considerations and pH limitations of the stationary phase being used to carry out the separation. A working eluent pH range for most silica-based materials is 3–8.5. For short periods of time or when using some of the sterically stabilized bonded phases, this range may be exceeded. However, in doing this, it should be recognized that once phase-loss begins, it proceeds at an increasing

\[\text{Figure 5} \ (a) \text{ Predicted equilibration rates under NP conditions for a } 4.6 \text{ mm inside diameter (i.d.) } \times 250\text{ mm column (i.e. containing 4 g silica with a surface area of 500 m}^2\text{ g}^{-1}\text{ and five silanol groups per square nanometer). rate as the underlying substrate undergoes hydrolysis. Initially phase-loss results in slowly decreasing retention and increasing peak asymmetry and, subsequently, it can lead to complete breakdown of the underlying silica matrix. The manifestation of this is column voiding and erratic peak shapes. Refilling the column with additional packing material may provide a short-term solution to some of the more severe peak-shape problems, but it will never return the column to its original level of performance as column breakdown proceeds by phase-loss and chemical and physical degradation of the porous matrix.

In cases where the analyte or analytes are very polar, their interactions with simple alkyl phases under RP conditions may not lead to sufficient retention to resolve the analytes. Under these conditions, alternate more polar phases, such as cyanoalkyl and aminoalkyl materials, may be useful. A good example of this strategy is the separation of simple carbohydrates using amine-type phases. Alternatively, very good separations of polar solutes sometimes can be obtained on unmodified materials, such as silica, using NP chromatography.

### 1.4 Establishing the Starting Eluent Conditions

There are two basic strategies for establishing the starting eluent conditions. One of these involves an isocratic approach and the other a gradient-elution approach. The isocratic approach starts with a solvent with high eluting power, which is systematically decreased by increments in subsequent separations. In the case of RP conditions, the eluent contains a high level of the organic cosolvent. In order of usage and increasing elute strength, the three principle organic cosolvents are methanol, acetonitrile, and tetrahydrofuran. It is not uncommon to start with nearly 100% of the organic component for highly hydrophobic compounds. For NP methodology, the scouting experiment begins with a high level of the polar modifier (say 20–30% 2-propanol) added to the nonpolar carrier eluent (e.g. hexane). In carrying out the isocratic approach, it is important that the eluting strength of the initial mobile phase is high enough so that all compounds to be separated will elute quickly from the column, and that changes in the eluent’s composition are made systematically. For RP methods, a 10 or 15% decrease in the organic eluent component provides a rapid means of arriving at an appropriate range of starting conditions and, for NP eluents, halving or approximately halving the polar modifier’s concentration provides an adequate change.

A useful quantitative scale (i.e. the eluotropic series) for selecting solvents is based on the work of Snyder and colleagues who examined how strongly solvent molecules adsorb to polar substrates. Although this scale was developed initially for alumina, it has been modified for silica. Experimentally it is often helpful, once three or four experiments are carried out, to make a simple plot of ln $k'$ versus the percentage of organic component in the eluent. An extrapolation of this plot, which in many cases is linear or nearly linear, provides a convenient way of predicting the retention profile of a compound over a broader range of eluent compositions or in fine-tuning the selection of a eluent between compositions tried. This is illustrated in Figure 6 for the separation shown in Figure 7.

When employing the gradient-elution approach as a scouting technique, one starts with a mobile phase of low eluting power and programs its strength to increase with time. Often a 10–15-min profile is a good scouting time.

![Figure 6](image-url) Retention data for the RP separation shown in Figure 7: (a) shows changes in $k'$ versus percentage methanol in the eluent; (b) shows changes in ln $k'$ versus percentage methanol in the eluent.
From the gradient profile it is possible to predict starting conditions. This is illustrated by the gradient profile shown in Figure 4 and the respective data summarized in Tables 1 and 2 for the NP separation of tolmetin. The predicted starting conditions from an extrapolation of the gradient at the time a particular solute elutes from the column is listed in the last column of Table 2. The published isocratic conditions are summarized in column two. The predicted and actual conditions are in good agreement. Although not illustrated, this same strategy also is applicable for the selection of starting RP isocratic conditions from a gradient profile that is run from high aqueous conditions to high organic conditions.

In using either the isocratic or gradient approach to predict an initial set of mobile phase conditions, the practicing chromatographer is faced with the following question: “How does one know if all compounds elute from the column?” Given a known set of analytes to be resolved, this is easily evaluated. However, given a truly unknown sample or an analyte in a complex matrix, this question is more difficult to answer. Unknown/ghost peaks or slowly drifting baselines often reflect the elution of highly retained compounds. This is often advisable to use thin-layer chromatography (TLC) as a quick screening tool. Under most conditions, if a compound shows some level of migration (even if it is only a very small amount) under a given set of TLC development conditions, then it will be eluted from an equivalent HPLC stationary phase using a similar mobile phase.

1.5 Isocratic versus Gradient Methods

Although it is not always possible to develop isocratic methods for every assay, they tend to be more reliable and less expensive and, as exemplified by the number appearing in the literature yearly compared to the number of gradient procedures, they are the first choice in simple-component assays. Additionally, in many cases they are carried out using relatively simple hardware, requiring the operator to blend the eluent off-line. Because of the popularity of the RP methodology, this operation most often involves the preparation of binary mixtures of either methanol and water or acetonitrile and water. For the trained chemist this is a very simple procedure of measuring a known amount of each component and carefully combining them to arrive at the correct eluent composition. Likewise, to the trained chemist, volume changes due to mixing and preferential enrichment of one of the two components are well-known concepts if one component is added directly to the other in the same volumetric vessel. However, it is not uncommon for individuals who are less familiar with these concepts, first to add a given amount of one of the components to a graduated cylinder followed by the direct addition of the second component. This latter practice should be avoided as it can lead to mixing errors and measurable variability in the chromatographic separation. This is illustrated in Figure 8 for the separation shown in Figure 7 and the elution relationships in Figure 6. A 1-mL mixing error, shown by the dashed lines intersecting at points b, results in a very significant change in $k'$. In cases where gradient methodology is necessary or at least more convenient, an added consideration in the optimization is selection of an appropriate profile in terms of linear, concave, or convex addition of the stronger

eluent component. Carrying out the initial separation with a linear gradient profile is often a good starting point. Based on this the gradient can be optimized to enhance the resolution of compounds in the initial part of the chromatogram by employing concave addition of stronger eluent components. Conversely, if the later peaks need additional resolution and the early peaks are well separated a convex gradient is used.

2 SAMPLE PREPARATION

2.1 Analyte and Matrix Considerations

One of the most challenging steps in any analysis, including those developed for assaying pharmaceutical products, is often conversion of the target compound into a form suitable for carrying out the chromatographic separation. In many pharmaceutical products, it is not unusual for the analyte to be present in combination with a variety of coadditives and, in the case of biological samples, at differing concentrations depending on source and disposition. This, coupled with physical constraints such as low volatility and thermal instability, has made HPLC methods the most widely used approaches for the quantization of pharmaceuticals in complex formulations and biologicals such as plasma, urine, and bile. Likewise for these same reasons, RP chromatography is especially well suited for these types of samples due to its ability to separate the analyte of interest from a wide range of contaminants. Nevertheless, sample pretreatment steps are usually necessary in order to convert the analyte into a form where the active ingredient is present at suitable concentrations and/or is free of contaminants and particulate matter that can interfere with the separation or damage the column and hardware. Even in cases where the separation can be carried out almost directly, (i.e. for formulations that can be chromatographed after a simple dissolution or dissolution/centrifugation steps) more extensive sample clean-up may be advisable in order to extend column lifetime. Ideally, the pretreatment steps should be rapid and inexpensive. Alternatively, in certain instances it may be more cost-effective to use a precolumn or to sacrifice column lifetime for speed and convenience.

2.2 Sample Work-up

In selecting the best set of pretreatment conditions, the analyst must first consider the physical state of the sample and its complexity. Clear liquids and capsules (i.e. analytes contained in a matrix that is free of particulate matter, dyes, and other coadditives) are generally the simplest types to analyze as either an aliquot of the liquid or a known amount of the powder can be diluted with the mobile phase or a compatible solvent containing an internal standard. Single-dosage forms such as capsules and tablets are analyzed either directly (i.e. to evaluate tablet-to-tablet uniformity) or after they are ground into a fine powder in order to obtain a homogeneous and representative sampling (i.e. composite assays). Many times the resulting formulations are dissolved in a suitable solvent (i.e. a solvent where the analyte is readily soluble and which is miscible with the mobile phase) and any suspended materials removed by centrifugation or filtration. Subsequently, a known aliquot of the supernatant or filtrate is diluted using a solvent containing the internal standard. Selection of an appropriate internal standard generally involves finding a compound that is similar in structure to the analyte and one that elutes near it in the chromatogram. As noted above, for RP methods a methyl homolog is often a good choice, if available, because it will have similar detection properties to the analyte and its retention will be predictable. If the homolog selected contains a larger number of carbon atoms than the analyte, it will elute later in the chromatogram. Conversely, if it has fewer carbon atoms, it will elute earlier. Likewise, a structurally identical or similar compound containing a hydroxyl group is also a good candidate for an internal standard and should elute more quickly than the analyte under RP conditions.

More complex samples typically require greater preparation, such as the removal of particulate matter by centrifugation or filtration or matrix proteins from biological media via precipitation with acetonitrile, ethanol, or trichloroacetic acid. These pretreatment steps are usually followed by some type of extraction in order to further isolate the analyte from soluble formulation coadditives.
or biologicals that will either interfere with the assay or foul the column. Traditionally, liquid–liquid extraction has been the method employed most often, and for many applications this continues to be a useful approach, especially for more concentrated samples and when there are distinct differences in the solubility and equilibrium properties of the analyte from those of the contaminants. The disadvantages of liquid–liquid extraction procedures are that they are time-consuming and utilize relatively large volumes of solvents which can be expensive to purchase. Similarly, disposal of the solvent can add considerable cost to the assay and, for more dilute analytes, additional concentration steps (e.g., evaporation) often are required prior to injection of the analyte.

Alternatives to liquid–liquid extraction include adsorption and partitioning methods to concentrate the analyte from the matrix. Partitioning methods, particularly modern solid-phase extraction (SPE), have become popular and increasing in use because they remove particulate matter with concomitant sample concentration, can be carried out on small sample volumes, and are applicable to a wide variety of samples in terms of their physical and equilibrium properties. These are attractive features, especially for biological fluids that are limited to small volumes. A further advantage of SPE is that it typically can be carried out rapidly using minimal volumes of the elution solvents. Further discussions on this topic may be found elsewhere.

Choosing an SPE sorbent is analogous to selection of an appropriate HPLC packing and depends on the solubility and equilibrium characteristics of the analyte as well as those of the sample matrix. Materials for SPE are chosen such that the analyte(s) of interest is either retained while the impurities pass through the cartridge or, conversely, the analyte(s) passes through the cartridge and the impurities are retained. The first approach is often preferred, because it can be used to purify and concentrate the analyte in one step. In the sample-retained mode, when the analyte is more hydrophobic than the sample matrix, NP-type sorbents are logical choices. Under this set of conditions, highly polar analytes are retained while less polar impurities can be made to pass through the cartridge. However, when the analyte is more hydrophobic than the sample matrix RP sorbents will selectively retain it with high efficiency and unwanted polar interferences can be made to elute. The reverse strategy is applicable when operating in the analyte-nonretained mode.

3 METHODS OPTIMIZATION

3.1 General Trends

Since the late 1970s an important trend in the area of pharmaceutical development has been the ever increasing use of HPLC, especially RPLC. Thousands of compounds are analyzed daily by RPLC and new agents are continually under development which will use RPLC because of its ruggedness compared to other separation modes such as normal-phase liquid chromatography (NPLC), the solubility of many drugs in hydro-organic eluents, and the selection and optimization of conditions are easier. A close inspection of the recent pharmaceutical literature reveals that by far the most typical set of RP conditions used employ either 150- or 250-mm columns packed with octadecyl or octyl bonded phases. These are used in combination with an isotropic mobile phase prepared from either water–methanol or water–acetonitrile and with the addition of secondary compounds to control solute ionization and to correct for nonideal surface effects.

3.2 Controlling the Chemical Equilibria

The most often used eluent additives are simple buffers, added to control the protonation and deprotonation of ionizable compounds and hence their retention properties. This is easily illustrated by the separation of a series of simple fatty acids with the general structure RCOOH. As these homologs contain the same functional group but again vary only in terms of the length of the alkyl chain, one would want to enhance (maximize) the interaction of the alkyl chain with an alkyl bonded phase by controlling the solute’s dissociation. Experimentally, this is accomplished by adjusting the pH of the eluent to about 1–1.2 pH units below the pKₐ of the carboxyl group which is approximately 4.7. When the eluent is buffered to 3.5–3.7, the solute exists predominately in its protonated, uncharged, form and its retention is governed by strong interactions between the nonpolar alkyl portion of the molecule and the immobilized alkyl chains of the bonded phase. There are many examples of pharmaceutically important agents which can be conveniently separated via relatively simple RP methodology by controlling the eluent’s pH. These range from common products such as aspirin and ibuprofen to related analgesics or anti-inflammatories such as fenbufen, flurbiprofen, ibufeac, ketoprofen, and the anticonvulsant valproic acid.
Figure 9(a) illustrates the relationship between retention and pH for simple monoprotic organic acids. In the deprotonated form (RCOO\(^-\)), the solute elutes quickly from the column, whereas in the protonated form (RCOOH), it is retained to an increasing degree based on the aliphatic portion of the molecule. The mirror image of this behavior is observed for basic solutes. In the fully protonated form, the relationship between retention and size (i.e. the carbon number) of the aliphatic portion of the homolog is logarithmic. A plot of ln \(k'\) versus carbon number is linear with a slope related to incremental methylene selectivity (Figure 9b). Similar relationships also are obtained for other classes of solutes and the retention for a given series is often easily predictable from a simple plot of ln \(k'\) against the carbon number. The substitution of a series of nonpolar groups in place of methylene units also results in similar incremental additivity. Likewise, an increase in the hydrophobic character of a series of homologs, such as through the addition of an aromatic ring, results in increased retention as illustrated by the parallel relationship that is offset to higher retention values for the alkyl phenols (Figure 9b, line a) compared to the fatty acids (Figure 9b, line b).

A simple rule is that by decreasing the charge (i.e. by dissociation) of the solute under common RP conditions one increases the interaction of the solute with the stationary phase, hence increasing retention and the possibility of resolving like compounds. As such, the preferred set of conditions for the separation of the compounds shown in Figure 9, as well as with other simple cases where only a single monoprotic group is present (such as the acid drugs shown in Scheme 1) or at least similar groups are involved, is in the plateau region of the curves. However, once the eluent pH is adjusted to this region, further adjustments to lower pH will have little effect on the quality of the separation, but will lead to increased chances of phase instability and decreases in performance of the column. Unfortunately in some cases, because of column stability considerations, the pH of the eluent cannot be adjusted low enough.
and tetraalkyl (up to C₄) ammonium salts. Although the heterogeneity). Inherent to all of these types of phases is the nature silica-based packings, an important controlling parameter. Irrespective of the synthetic routes used to produce 3.3 Nonideal Column Effects

Complex structures should be about 3.5, as the only compounds in Scheme 1, as well as the remaining more fenoprofen. Additionally, it is reasonable to suggest that an assay developed for ketoprofen might be a useful starting point for fenoprofen. Nevertheless, for the latter set of compounds, because they are structurally similar, it is reasonable to suggest that the pH of the eluent for separating the first six compounds in Scheme 1, as well as the remaining more complex structures should be about 3.5, as the only important structural feature requiring eluent buffering is the carboxyl group.

3.3 Nonideal Column Effects

Irrespective of the synthetic routes used to produce silica-based packings, an important controlling parameter inherent to all of these types of phases is the nature of the substrate surface (i.e. its chemical and structural heterogeneity). Porous silica is an amorphous material with a three-dimensional structure that contains several types of polar silanol groups on its surface. The distribution of these groups and morphology determine the extent and heterogeneity of the resulting bonded phases. The number and distribution of silanols change depending on the synthetic route that is employed to produce silica, as well as post-synthesis processing (i.e. thermal treatment and rehydration) to mechanically stabilize the material. Additional information on the physical and chemical properties of silica may be found elsewhere.

When silicas are produced, it is not unusual to obtain materials that are equivalent based on an examination of their macroscopic properties, such as total number of silanol groups, surface area, porosity, etc. yet dramatically different in terms of microscopic heterogeneity which influences the nature of bonded phases produced from such materials. To the practicing chromatographer, this problem manifests itself as manufacturer to manufacturer and batch to batch differences in column performance for a given stationary phase. Additionally, this problem is exacerbated for solutes that have polar functional groups that can interact strongly with residual silanols such as amines and heterocyclics. These are not uncommon types of compounds encountered on a daily basis in the pharmaceutical industry.

In order to minimize the residual silanol problems, one of four approaches is generally used, these being post-action end-capping, preparation of sterically blocking phases, electronic manipulation of the attached surface groups, and the use of mobile phase additives. End-capping involves a resilanization of the column with a small reactive silane such as trimethylchlorosilane following the initial bonding process. The second approach utilizes surface ligands that can sterically block silanol accessibility. The third approach, electronically manipulated phases, involves imbedding a functional group within the bonded chain’s interior that can interact with neighboring residual silanols (e.g. alkylamide phases). Each of these three approaches has allowed manufacturers, as well as researchers, to prepare columns with enhanced chromatographic performance. Unfortunately, not all peak-tailing problems have been eliminated by these and, as columns age, the problem of exposed silanol groups increases even for high-performance bonded phases. Many of these unwanted effects can be eliminated or at least minimized through the use of secondary mobile phase additives.

3.4 Use of Secondary Additives to Enhance Performance

Although the performance of commercially available bonded phases has improved dramatically in recent years, there are still many RP applications where residual silanol activity leads to unacceptable chromatograms in terms of severely tailing peaks. Such problems can usually be addressed by the addition of compounds to the eluent that dynamically modify the surface by a competitive sorption mechanism, and hence act to suppress undesirable interactions that can arise between basic solutes and residual silanols. This process is sometimes referred to as silanol masking and the agents used to do this are strongly sorbing compounds (i.e. molecules that contain a polar head group and a nonpolar tail) that do not interfere with detection. The most commonly used compounds to

(Redrawn from ref. 48 with permission.)

mask silanol activity, and hence improve peak symmetry, are alkylamines;[47] however, in a few cases other compounds, such as perfluororalkyl surfactants, have been employed.[48,49]

The chromatograms appearing in Figure 10 illustrate the dramatic effect a masking agent can have on the separation performance of solutes (e.g. simple aromatic amines) that interact strongly with residual silanol groups. Both separations were carried out on a standard commercial octyl bonded phase using 60:40 methanol–water. However, chromatogram (a) was obtained without the addition of a masking agent and chromatogram (b) was obtained with a masking agent present in the eluent.[47]

Within the realm of pharmaceutical drug analyses, two techniques currently dominate the field. High-performance liquid chromatography (HPLC) is at the forefront, followed somewhat distantly by gas chromatography (GC). HPLC is more prevalent than GC owing mainly to the heat-labile nature of the majority of drug substances. Still GC continues to play a very active role. In comparison to HPLC and GC, combined, the frequency of use of other techniques is quite small. Perhaps the major reason for this is that chromatography not only involves qualitative and quantitative detection of targeted species, but also provides a medium for isolating these analytes from potential interfering impurities prior to measurement. The proficiency of this combination is unparalleled by any other blending of means to clean up a sample and detect...
the target compound. These more prominent techniques are often complementary, although each has its own strengths and limitations. General guidelines are given to assist the chromatographer to elect HPLC and/or GC for a particular separation. Considerations for choosing hardware type and sizes, solid support and bonded phase are presented. Particular emphasis is placed on the latest, which is of primary importance for obtaining rugged methods. The reader is directed towards optimum phase selection based on the compound of interest’s functional group type, or by its drug activity classification (e.g., barbiturate, cardiovascular, etc.). Assistance in developing new methods frequently arises when starting with an existing published method for a compound with similar structure. This article provides 514 references for more in-depth separation information. In addition, background knowledge on bonded-phase chemistry, chromatographic modes of separation, approaches to chromatographic chiral drug discrimination and processes for developing rugged methods is contributed.

1 CHOOSING THE SEPARATION TECHNIQUE – GAS CHROMATOGRAPHY VERSUS HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

1.1 Introduction

GC and HPLC are generally considered to be complementary techniques. Choosing one over the other is often dictated more by equipment availability and familiarity than by which technique is better suited for a particular application. However, guidelines exist for the chromatographer to make educated choices for the optimum system, when both means are available. Traditionally, GC chromatograms have provided an order of magnitude more theoretical plates than HPLC, although newer HPLC columns packed with smaller particles approach GC performance in that regard. Higher theoretical plates enable easier separations of more complex samples that contain numerous constituents. A chromatogram containing about 15 peaks would be considered complex for most HPLC separations, but is more commonplace for GC chromatograms. HPLC is capable of separating a wider range of analytes than GC. Earlier, GC was capable of detecting a wider range of analytes with better sensitivity than HPLC. However, this advantage has diminished with the advent of light scattering detectors, and “hyphenated technologies” such as liquid chromatography/mass spectrometry (LC/MS) and liquid chromatography/nuclear magnetic resonance (LC/NMR). In fact, Gelpi postulated that LC/MS is replacing gas chromatography/mass spectrometry (GC/MS) analyses for drug metabolism, therapeutic drug monitoring (TDM) and pharmacology, since the former is applicable to highly polar and larger molecular weight compounds without complicated derivatization and handling procedures.

There is evidence that HPLC is currently the more popular technique and is growing faster than GC. In a 1995 survey, total HPLC instrument sales ($840.00 million) were higher than GC instrument sales ($575.00 million). A 1997 survey of analytical instrument end-users reported that HPLC (1600 units) was the main technique used, followed by GC (1300 units). Other techniques, such as UV/VIS (ultraviolet/visible), electrophoresis, FTIR (Fourier transform infrared) and AA (atomic absorption) were less utilized than HPLC or GC. Around 50% of HPLC owners surveyed expected increased HPLC usage over the next five years. In contrast, about half of the GC users considered their technique to be mature with few new applications emerging. Within the pharmaceutical industry, HPLC was the most commonly used instrumentation in the laboratory (35%) followed by GC (15%). Pharmaceutical QA/QC laboratories employed HPLC (49%) in higher percentage than GC (19%), and HPLC was expected to demonstrate a significantly higher growth rate than GC over the next five years.

In reflection of the above surveys, this article focuses proportionally more on HPLC than on GC pharmaceutical separations. Nevertheless, it appears that GC will remain an important tool in pharmaceutical analyses for some time.

It is important to note that the references provided in this work are by no means an exhaustive coverage of the available literature for the given topics. Rather, they serve to exemplify distinguished points and provide starting conditions for the analyst in methods development of unique compounds.

1.2 Sample and Other Considerations

Perhaps the most important points in choosing between GC and HPLC methodology are the volatility and thermal stability of the sample. Nonvolatile samples are not suitable for GC analyses unless they are derivatized to a more volatile form. Gouw and Jentoft estimated that only 15% of known compounds can be volatilized without thermal degradation. There are no such restrictions with HPLC, which is at least part of the reason for the increased popularity of HPLC over GC in pharmaceutical separations. Sample volatility is dependent on the composition and structure of the compound and its molecular weight. As a general rule of thumb, pharmaceutical chemicals above about 200–300 molecular weight and those containing polar functional groups are better suited for HPLC analyses.
Derivatization for GC analysis is accomplished by reducing a nonvolatile sample’s polarity. Electrophilic and other derivatization reagents are commercially available from a variety of chromatography companies and are usually shipped in sealed ampules to prevent atmospheric moisture from deactivating the reagent. Some of the more popular reagents include silanes, acylation reagents and alkylation reagents. They react with compounds that contain exchangeable or active protons (protic samples), such as alcohols, thiols, carboxylic acids and amines, to form the corresponding ethers, thioethers, esters and amides, or with aldehydes and ketones to form oximes. In addition to increasing sample volatility, many derivatized samples also exhibit higher detection sensitivity, selectivity and chemical stability than the parent sample. Disadvantages in derivatized sample methodology include the added preparative time and expense, and the need to determine the percent yield of the derivatized product for quantitative measurements. Reproducible derivatizations may be particularly difficult with samples that contain more than one reactive site. By-products and side products may also co-elute and interfere with chromatographic peaks of interest.

Although not as prevalent as in GC, HPLC derivatizations are also occasionally performed. For strategies and synthetic methods in pharmaceutical HPLC sample derivatizations, see Ahuja(12) and Danielson et al.(13).

Although the analyte itself may be volatile, the sample matrix may preclude use of GC analyses. Nonvolatile components can build up within the GC column, affecting subsequent chromatographic performance, or even plug the column. Prepurification by solid-phase extraction (SPE), membrane filtration, flash chromatography and other procedures are viable options, but add to analysis time and cost.

Determining residual solvents in drug substances is an application particularly suited for GC analysis. Twenty-two common process solvents were determined by Kersten(14) and the results were not affected by weakly acidic, weakly basic or neutral drug matrices.

Analyte stability may play a role in the choice of technique. Heat-labile compounds may be more suited for HPLC than GC. GC may be more appropriate than HPLC for compounds that can potentially react with silica surface silanols. As discussed below (section 3.3), nonsilica HPLC phases are available to extend the useful range of HPLC packings. Notwithstanding, sample stability of analytes is often overlooked in methods development, but is often an important consideration.

1.3 Literature Comparisons

The complementary nature of HPLC and GC techniques is exemplified by the separation of atropine [51-55-8] and obidoxime [7683-36-5] parenteral solution, an emergency treatment for toxic organophosphates poisoning. Pohjola and Harpf(15) found that simultaneous GC analysis required tedious and time-consuming sample preparation owing to their different extraction properties, and obidoxime is thermally labile. Retention characteristics differed widely for the two components, making simultaneous HPLC analysis unsuccessful, even under gradient conditions. The authors settled for a GC method for atropine and an HPLC method for obidoxime.

Bile acids analysis generally gave identical results by GC and HPLC/UV (high-performance liquid chromatography/ultraviolet). However, Scalia et al.(16) chose HPLC as the more convenient system for routine analyses since it bypassed derivatization reactions required for GC analysis. GC was then used for verification of HPLC results.

Similarly, Guinebault et al.(17) picked HPLC as the faster and simpler technique for the determination of cicloprolol [63659-12-1]. The GC/EC (gas chromatography/electron capture) method gave somewhat lower levels of detection at 1 ng mL\(^{-1}\) (compared to 5 ng mL\(^{-1}\) for the HPLC fluorescence method), and was used for lower level samples.

Regarding TDM, Mehta(18) discussed several advantages of HPLC over GC. The former technique was considered to be quicker and more widely applicable. Sample cleanup was simpler, which is important for TDM. GC methods are often limited to 1-μL injections, whereas up to 100 μL can be injected on an HPLC column. Furthermore, HPLC is more adaptable to automation than GC.

Qualitative and quantitative results by HPLC analyses of nitrosamines were found to be in agreement with GC analyses as reported by Röper.(19) HPLC/UV detection of diethylnitrosamine at 254 nm matched the sensitivity of GC/FID (gas chromatography/flame ionization detection). The significant advantage in this study was that the HPLC method could be run in half the time that it took to run the GC method.

A review of HPLC and GC analyses of basic neurotransmitters and their metabolites was recorded by Yi and Brown.(20) Although the report summarized work published before LC/MS reached a level of commercial importance, HPLC was already seen as gaining on GC/MS, in use for routine analysis of diseases.

Suitability studies between HPLC and GC techniques, such as those described above, are not directly comparable. Contrarily, the conclusions obtained from such an endeavor rely heavily on the particular equipment, conditions and methodology employed. They serve only to introduce the types of problems that might be encountered in investigating a particular HPLC or GC technique. In a practical sense, the actual choice of one technique over the other might best be accomplished by...
finding published work on how similar mixtures were analyzed, keeping in mind the considerations discussed above (see section 1.2).

1.4 Ideal Methods Development

The ideal chromatogram presents impurity peaks eluting at or near the solvent front, followed by peaks of interest emerging with baseline resolution (defined by $R_s = 1.5$) and no more. This scenario provides the best approach in obtaining simple, relatively inexpensive, rugged, reproducible and fast methods. Although “real” sample mixtures rarely can be separated so perfectly, the professional chromatographer should strive to procure quality in developing as close to the ideal method as possible. Many pharmaceutical methods are Food and Drug Administration (FDA)-regulated, placing severe restrictions on analytical modifications. As a result, analysts are often locked into running poor methods for years to come. It is very time-consuming and expensive to revalidate or develop a new method. The prudent choice is to develop good methods up front, although the necessary time often is not afforded to the analyst. As a result, analytical laboratories specializing in cGMP (continuous good management practices) methods development have sprung into existence, particularly in the 1990s, to provide this needed service. The most versatile laboratories have expertise in both HPLC and GC for acquiring sound methods. For strategies on methods development, see section 5.3.

2 COLUMN SELECTION

2.1 Tubing Choices

Stainless steel (SS) tubing is the most widely used tubing for HPLC columns. They are rigid and can easily withstand packing pressures that typically go up to 10,000 psi ($6.9 \times 10^7$ N m$^{-2}$). The material is relatively inert to a wide variety of solvents and chemicals. A smooth internal diameter (ID) of the SS tube can be honed, which is desirable for packing high-efficiency columns. Root mean square (RMS) units are used in measurement of smoothness of the tubing ID, by a profilometer instrument. A RMS of about 16 or better is standard for 4.6 mm or larger SS HPLC columns, 2-mm ID columns are generally 32 RMS, and 1-mm ID columns are usually 40 RMS or worse.

Reduced bore SS tubes of about 2 mm or less are more difficult to hone and quality control than larger bores. Some are coated with a glass lining, which may provide a smooth internal surface enabling higher efficiency in the packing process. Antithetically, the glass-lined tubes are somewhat susceptible to cracking, which critically inhibits packing good columns. Other commercial SS tubes are micropolished with an abrasive mixture that is forced through the column.

Particularly in some protein and peptide separations, polyetheretherketone (PEEK®) tubing is thought to provide a more inert surface than SS. PEEK® column frits (used to hold the HPLC packing material in the tube) may be employed in conjunction with PEEK® columns. Although PEEK® is a “hard” plastic, it is less rigid than SS and it is often more challenging to pack PEEK® columns with the same efficiency as SS columns.

A newer approach to produce smooth, inert HPLC tubes entails coating a proprietary silicone-containing layer of material known as Silcosteel® onto the ID of the SS tube. The strength and ruggedness of the SS tube is retained and excellent improvement in deactivation is realized. The coating treatment was originally developed for deactivating fused silica and flexible SS GC columns and also for air monitoring SS canisters, particularly for use with invasive sulfur-containing samples. Its use has been extended to deactivate bonded silica HPLC particles.

Early GC capillary columns, since the 1950s, were largely made of SS. They were rugged and flexible, but lacked inertness. Latter developments in packed glass columns improved inertness at the expense of being more fragile. In 1979, the more rugged and flexible fused silica tubing was discovered, which was considered to be a breakthrough in GC technology. Capillary fused silica columns are even more inert than glass columns. One limitation they do have is that they become brittle at temperatures exceeding 350°C. Some improvements in thermal stability have been attempted by devising aluminum cladding or high temperature polyimides as an outer column coating. Another approach was the aforementioned invention of silica-lined, thin-walled, SS capillary columns.

2.2 Dimensions

Majors reported in a 1994 survey that the 250 × 4.6-mm column (53.2%) is the most popular dimension used, followed by the 150 × 4.6-mm (40.9%) size. The 4.6-mm ID columns are popular partially because system peak bandspreading is less of a factor for large ID columns compared to small ID columns according to the relationship in Equation (1):

$$\sigma_{\text{total}}^2 = \sigma_{\text{sys}}^2 + \sigma_{\text{col}}^2$$

where, $\sigma_{\text{total}}^2$ is the total bandspreading, $\sigma_{\text{sys}}^2$ is the bandspreading due to HPLC system effects and $\sigma_{\text{col}}^2$ is the bandspreading due to HPLC column effects.
Thus, as column ID decreases, the $\sigma^2_{\text{col}}$ term becomes smaller and $\sigma^2_{\text{sys}}$ contributes proportionally more to the total peak bandsprading. Columns down to about 3-mm ID typically do not require significant changes in an existing HPLC system to obtain peak efficiencies similar to a 4.6-mm ID column. However, column IDs of 2 mm or less may require changing the HPLC hardware to minimize the now dominant $\sigma^2_{\text{sys}}$ term. This may include switching to narrower ID and/or length connective tubing, replacing the flow cell with one of smaller volume, and/or using a pump designed to deliver accurate slower flow rates.

Approximate optimum flow rates for the corresponding column ID are shown in Table 1. Note that regardless of the column ID, the linear velocity remains constant for optimum efficiency. The optimum linear velocity is about 0.15 cm min$^{-1}$ in HPLC separations. This value can change slightly depending on the column packing material. The advantages of using smaller ID HPLC columns include solvent savings (Table 1) and increased sensitivity for samples of limited quantity.

Larger ID columns are desirable for semi-preparative (about 10-mm ID) and preparative (about 20-mm ID or larger) separations. Mobile phase and other chromatographic conditions are first explored on a smaller ID analytical column to save time, solvent and costs. After desirable conditions are found, increasing sample loads are run to determine the "overload" point. Overload is not strictly defined, but is relative to the needs of the analyst. It is the highest load that can be run before the desired separation is lost. For chemists pursuing 98% purity for drug candidate testing, near baseline conditions may be required. Alternatively, a marginal separation may provide the required purity level by the shave/recycling process (Figure 1).

Once the analytical column scouting work has been completed, the following calculations in Equation (2) and Equation (3) may be used to ascertain the corresponding flow rate and load, respectively, for the semi-preparative/preparative column chromatography runs:

$$F_p = F_a \frac{D_p^2}{D_a^2}$$  \hspace{1cm} (2)

$$S_p = S_a \frac{D_p^2 L_p}{D_a^2 L_a}$$  \hspace{1cm} (3)

where $F_p$ is the flow rate of preparative column, $F_a$ is the flow rate of analytical column, $D_p$ is the diameter of preparative column and $D_a$ is the diameter of analytical column.

(Note that this calculation was used to determine the optimum flow rates in Table 1).

It is important to note that Equation (2) and Equation (3) do not necessarily hold true unless the packing material in the preparative column is identical to that in the analytical column. Some chromatographers prefer to use a larger particle diameter (for example, 12-µm preparative particles instead of 5-µm analytical particles) in preparative columns to reduce backpressure, and because of their lower initial cost. However, preparative separations using small particle sizes are not only feasible, but also can be advantageous. Substantially higher efficiency preparative columns can be obtained, and faster flow rates may be used without significant sacrifice of efficiency.\(^{(22)}\)

The larger sample amounts injected on preparative columns may cause the UV (ultraviolet) signal to go off scale, even at maximum attenuation. If a nonlinear setting is not available on the detector, the signal may be reduced by setting the detector wavelength away from the UV$_{\text{max}}$ (ultraviolet maximum) of the analyte.

Theoretically, column ID does not affect column efficiency. In practice, however, column IDs of about 2 mm or less are more difficult to pack and generally generate about 10 000–20 000 plates m$^{-1}$ lower efficiencies than the corresponding larger ID columns. In contrast, theoretical plates increase in direct proportion to column length. Thus, a 200-mm length column should provide twice the efficiency of a 100-mm column, all other factors being equal. For routine analytical work, lengths of 150 mm or 250 mm are commonplace. Lengths of 50 mm or less are popular for fast separations and may be packed with smaller particle sizes to boost the efficiency lost by using shorter column lengths. Sizes longer than 250 mm may be utilized to gain any needed efficiency to attain a preferred separation. Size exclusion chromatography (SEC) prevalently uses longer columns or two coupled columns to attain desired separations.

Regarding GC columns, the ID choice is primarily based on the concentration range of the targeted analytical compounds. Overall sample concentrations may need to be adjusted to fall within the linear range of the detector being used. The column ID is then chosen that can function within that range. Table 2 includes suggested column IDs based on sample capacity. Resolving power (measured by plates m$^{-1}$ or Trennzahl values) increases with decreasing ID (see Table 2). With very complex samples, the smallest ID column within the sample range capacity should be chosen. If samples are dirty, a wider ID column may be beneficial in reducing column plugging. Column IDs of 0.32 mm or 0.53 mm are recommended for splitless, direct or on-column injections to promote better sample transfer efficiency and increase quantitation. Instrument types and inlet systems may require certain flow rates, dictating the ID selection. Packed column GC inlet instruments are limited to 0.32 or 0.53-mm ID columns because their higher flow rates are essential to improve sample introduction, unless system modifications are introduced. Capillary injection systems accommodate any column ID Finally, instruments with sample valves and purge and trap inletting systems operate best with higher flow rates, which may be afforded by 0.53-mm ID columns.

Resolution increases with the square root of, and analysis time increases directly proportional to, the column length for isothermal separations. More than half of the columns used in laboratories are 30 m in length. Longer GC column lengths are standard for low-boiling complex mixtures, while shorter thicker filmed columns are popular in preventing peak tailing from highly active compounds. Shorter columns also tend to display lower bleed levels and have utility for fast separations of simple mixtures, or for extremely high-molecular-weight compounds.

### 2.3 Coverage and Film Thickness

Percent carbon values for HPLC bonded phases are frequently reported by commercial manufacturers as an indication of the hydrophobic retentivity of the packing. However, this can be deceiving. A better measurement is the coverage calculation, which in addition to percent carbon, also takes the particle’s surface area into consideration. The coverage value furnishes a gauge of phase ligand density, hydrophobicity, surface silanol availability, mixed mode silanol activity and possibly phase stability. These points are addressed in more detail below. Of the coverage formulas used by chromatographers, perhaps the most precise calculation is that introduced by Berendsen and de Galan\(^{(23)}\) as follows in Equation (4):

\[
\text{Coverage (µmol m}^{-2}\text{)} = \frac{10^6}{100 \times n \times 12.01 - (\%C \times (MW - 1))} \times \text{SA} \tag{4}
\]

where \(\%C\) is the percent carbon of bonded phase (measured by elemental analysis), \(n\) is the number of carbon atoms in one bonded ligand, MW is the molecular weight of bonded ligand and SA is the surface area of silica.

This formula addresses the fact that a proton was removed from the bonded silanol as depicted in Figure 2.

Coverage can also be an indicator of phase ratio (amount of solute in the stationary phase per amount of solute in the mobile phase). Increasing the phase ratio can, in turn, increase resolution by increasing the capacity factor term in the resolution equation (Equation 5). Higher coverage packings generally exhibit increased phase ratios, excluding situations where mixed mode separations play significant roles.

\[ R_s = \frac{1}{4} \times \alpha - \frac{1}{\alpha} \times \frac{k'_2}{k'_1 + 1} \times N^{1/2} \]  

where \( \alpha \) is the selectivity, defined as \( k'_2/k'_1 \), \( k' \) is the capacity factor of the peak and \( N^{1/2} \) is the square root of the number of theoretical plates for a particular packed column.

In GC separations, film thickness can be regarded as a reflection of the phase ratio. Thicker films are used for low-boiling compounds to increase retention and, thereby, resolution. Moderately thick films (1 or 1.5\( \mu \)m) are utilized for samples that elute between 100 and 200°C. Samples that elute up to 300°C can be run on standard films (0.25 or 0.5\( \mu \)m).

### 2.4 Stability and Reproducibility

Silica-based HPLC packings are still the most widely used phases. They possess excellent mechanical strength, are relatively inexpensive, can be easily modified to render desired chromatographic performance, and can be manufactured reproducibly with control of both particle and pore size distributions. One shortcoming is that they are limited to a pH range of about 2 to 7.5. Kirkland\(^24\) reported that higher pH conditions hydrolyze the siloxane backbone, while lower pH conditions hydrolyze off the bonded-phase moiety. Acid hydrolysis typically results in a loss of chromatographic retention with repeated injections, as bonded phase is gradually liberated from the column. Base hydrolysis maintains retention since the bonded phase attachment remains intact, but abruptly loses efficiency, when the silica backbone finally collapses.

Nevertheless, analysts continually push the pH limitations of silica in developing methods for difficult mixtures. Commercial column manufacturers have responded by developing technology to extend the useful pH range of silica packings. One strategy was to manufacture bulky side chains on the bonded phase in an attempt to hinder hydrolysis of the bonded phase sterically. The commercial product, Zorbax\(^25\) Stablebond\(^25\), reportedly increased acid stability. Another study applied larger 150-Å pore, pure silica particles (1 Å = 10\(^{-10}\) m), and high coverage bonding chemistry to obtain essentially the same level of acid stability.\(^26\) Advances in base stability of silica packings have also been reported.\(^27\) In addition, nonsilica packings are used for methods run at pH extremes (see section 3.3).

An investigation into commercially available modified silica HPLC packings will reveal that, almost without exception, bonded phases are prepared with no less than three carbons between the reagent silicon atom and any heteroatom present in the reagent. Thus, there are 3-cyanopropylsil phases, 3-aminopropylsil phases, 3-glycidoxypropylsil phases, etc. The reason for this is that spacers of less than three carbons result in an inherently less stable compound. A review of the stability of bonded phases was published by Unger.\(^28\)

There have been some claims that cyanopropyl bonded phases hydrolyze under acidic HPLC conditions to the corresponding propylcarboxylic acid as shown in Scheme 1. It is true that synthetic chemists use cyanohydroxylation to mask the eventual preparation of carboxylic acid moieties. Still, the cyano hydrolysis in synthesis deprotection procedures\(^29\) is persistently much more invasive than regularly practiced HPLC conditions. This author found no sign of cyano group hydrolysis of a cyanopropyldimethylhydroxysilane model under conditions ranging from pH 2 to pH 7, by proton NMR (nuclear magnetic resonance) or HPLC using chemical probes.

**Scheme 1** Hypothetical acid hydrolysis of an HPLC cyano bonded phase.
Ester groups are susceptible to hydrolysis by acidic mobile phases, which should be avoided with both ester bonded phases and/or ester analytes. Whenever practical, ester solutes should be run under neutral pH conditions.

There are commercial phases that are not covalently bonded to solid supports, but rather are “ionically” coated onto the surface of particles. These phases, such as some chiral cellulose packings, are strictly limited to certain types of solvent exposure. Even slight amounts of solubilizing solvent can ruin a column.

Reproducibility of HPLC bonded phases is largely dependent on the replication of the bare silica. Bonding chemistry is also important. Monofunctional bonded phases are inherently easier to reproduce than di- and trifunctional bonded phases (see section 3.2). Some commercial difunctional and trifunctional bonded phases (see section 3.2) contain residual alkyloxysilane or chlorosilane functionality following bonding. Under aqueous mobile-phase conditions, these residual reactive groups might slowly hydrolyze, resulting in an unstable baseline (bleed) over a long period of time, with constantly changing chromatographic performance. Even if a stable baseline can eventually be obtained, reproducibility of this product under similar bonding tactics is customarily poor. Commercial polymeric aminopropyl phases, used for sugar/carbohydrate separations, are prime examples of this type of hydrolysis problem.

HPLC and GC bonding reagents should be purified of any catalysts used in their formation before attachment to silica. It is very difficult to remove them afterwards. Their presence may cause unstable baselines, peak tailing or possible catalytic decomposition of some analytes (e.g., proteins).

Column bleed in GC phases ordinarily is larger for thick films than thin films of the same coating. The phases have varying degrees of inherent thermal stability depending on their chemical nature. Manufacturers routinely list proper operating temperatures, which should be followed to prevent phase degradation. Tolerable residual bleed normally occurs even at low temperatures owing to trace amounts of oxygen, metals, catalysts and other impurities that slowly degrade the polymer film.

The reproducibility of commercial brand stationary-phase performance over several years, whether HPLC or GC, should not be taken for granted. Welinder et al. describe some of the real-life enigmas associated with unannounced manufacturer’s phase alterations over time. The authors stress the importance of validation, GMP (good management practice), SOP (safe operating procedures) and QA/QC for the column manufacturer, who should be treated as a contract laboratory.

2.5 Phase Type

Pharmaceutical methods development, whenever possible, should be attempted on a reversed-phase (such as a C18, C8, phenyl, etc.) column. This is due to the simple hydrophobic mode of separation that is most familiar to the chromatographer. Reversed-phase separations are often rugged, and columns are relatively inexpensive and readily available.

The C18 phase (also called octadecylsilyl, or ODS phase) was one of the first modified silica types prepared, owing to the availability of the starting material rather than for any specific scientific motive. Its use rapidly gained in notoriety during the early years of HPLC and it remains the most popular phase today.

It is crucial to note that all commercial C18 phases are not alike. In fact, it can be favorably argued that no two C18 phases are alike. Figure 3 illustrates the vast possible differences in C18 brand column performance.

Shorter hydrocarbon chain reversed-phase columns may be used to reduce retention of highly adsorbed compounds. Phenyl phases add possible dipole:dipole or dipole:induced dipole interactions for another dimension in solute/stationary phase recognition. In particular, phenyl phases appear to have proficient selectivity of carbamates. Cyano phases are one of the best choices for basic pharmaceuticals, showing excellent peak shape and complementary selectivity to C18 phases. Cyano columns are also a good choice for steroids, and can be used under both reversed-phase and normal-phase conditions. De Smet and Massart found the cyano phase to be so versatile for normal- and reversed-phase separations of basic drugs, that they used it exclusively.

A modified C18 phase engineered for use under high aqueous mobile-phase conditions is of particular interest in reversed-phase retention of polar solutes. Traditional C18 phases contain hydrophobic chains that may fold under such conditions to avoid the hydrophilic mobile phase surroundings. Modified commercial C18 phases based on this concept adopt a similar fundamental strategy in introducing polar functionality close to the silica backbone. In this manner, the C18 chain, hypothetically, remains extended since there is a hydrophilic environment both in the mobile-phase volume and towards the solid support surface.

Newer reversed-phase columns include the intrinsically base deactivated (IBD) phases. They are categorized as those packings that contain a polar functional group within, or intrinsic to, the hydrocarbon chain (see Figure 4). The intrinsic heteroatom(s) apparently is involved in deactivating active surface silanols that would otherwise cause undesirable peak tailing of basic compounds. The heteroatom also appears to play a major role in selectivity, as reversals in elution order are
GAS AND LIQUID CHROMATOGRAPHY, COLUMN SELECTION FOR, IN DRUG ANALYSIS

Commonplace compared to C\textsubscript{18} phases. Solute mixtures of acids, bases and zwitterions can often simultaneously be separated with good peak shape for all solute types using simple mobile-phase conditions. Separations on this phase are somewhat more affected by small differences in mobile-phase composition than C\textsubscript{18} phases are, which may make developed methods slightly less rugged. However, some of these phase types show immunity to chain folding, similar to the modified C\textsubscript{18} phases described above. A few IBD phases are commercially available.\textsuperscript{(32)}

Another variety of reversed-phase column is the halogenated stationary phases discussed in section 5.6.

The most prevalent normal-phase columns employed in the pharmaceutical industry are the amino phase columns for sugar-containing drugs, saccharides, and so on, and the diol phase for polar compounds. The latter phase is regularly used in SEC, especially for proteins and large peptides (see section 4).

Ion-exchange columns are used for highly polar, ionizable drugs that cannot be retained by reversed-phase columns. Weak anion-exchange (WAX) columns contain an immobilized primary or secondary amine functionality that is positively charged at mobile phase pHs below the pK\textsubscript{a} of the amine (pH about 7.5 or less). Strong anion-exchange (SAX) columns contain a tertiary amine group that remains positively charged throughout the pH range. The WAX and SAX phases, therefore, are designed to retain anionic drugs (see section 4). Weak cation-exchange (WCX) phases carry a negatively charged carboxylic acid residue at mobile phase pHs around 6 or more. Strong cation-exchange (SCX) phases bear a negatively charged sulfonate group essentially throughout the pH range. Consequently, WCX and SCX phases are capable of retaining basic drugs (see section 4).

In summary, phase selection is primarily empirical. Quantitative structure–retention relationships (QSRR) studies have progressed in identifying at least one factor or descriptor responsible for a given reversed-phase HPLC separation, such as partition coefficient,\textsuperscript{(33)} electronic characteristic,\textsuperscript{(34)} solute bulkiness\textsuperscript{(35–37)} and shape.\textsuperscript{(38)} Yet many more descriptors may be involved in the final separation result. In one QSRR study, Kaliszan and Osmialowski\textsuperscript{(39)} identified 16 structural descriptors in addition to some polar descriptors. An excellent review of QSRR application to reversed-phase HPLC is that authored by Kaliszan.\textsuperscript{(36)}

Retention indices are used as indicators for choosing GC phases for classes of mixtures. For example, benzene serves as an indicator where aromatics or saturated hydrocarbons may elute using a particular GC phase. Similarly, butanol can be used as an indicator for where polar alcohols and aldehydes may elute. Coated GC phases may impart strong dipole and hydrogen bonding characteristics, such as the polyethyleneglycol

phase attraction for low-molecular-weight alcohols. This adds a powerful resolving mode for mixtures that would otherwise elute based solely on their relative boiling points, which may be too similar to resolve. In general, polar phases retain polar solutes longer than do nonpolar phases.

3 CHEMISTRY OF BONDED PHASES

3.1 Gas Chromatography Coatings

Most GC phases are constructed by coating a static or dynamic layer of polymerizable silica-containing reagent(s) on the inside wall of a tube and then polymerizing it in place by heat or other processes. Film thickness can be controlled by the original reagent concentration. The reagent may contain a variety of functional groups, each contributing a unique quality to the separation process. Figure 5 shows a few marketed phases.

3.2 Modified Silica Phases

The silica particle surface may contain chemical diversity including siloxanes, geminal silanols, vicinal silanols, isolated silanols, and metal contaminants (Figure 6). A surface chemistry variation between brands is one of the primary reasons why no two C18 packings chromatographically behave the same. Geminal and isolated silanols are thought to be the most active silanols in causing undesirable peak tailing. Metal contaminants, such as sodium, magnesium and iron, also play a role in activating silanols. Vicinal silanols, hypothetically, are indicative of a more homogeneous surface, and are less active.

Active silanols may actually improve peak shape for acidic solutes compared to a nonactive packing. These older “type A”, active silicas are not suitable for basic or zwitterionic compounds. Newer, “type B”, pure silica packings give superior peak shape for basic and zwitterionic solutes, and perform well for acids as well. Reviews covering the effect of silanols on basic compounds were composed by Nawrocki and Cox.

Traditional bonding chemistry involves covalently bonding a monofunctional, difunctional or trifunctional chlorosilane reagent to a surface silanol group in the presence of a tertiary amine proton scavenger, as shown in Scheme 2. Alkoxysilanes, such as trimethoxysilyl-, triethoxysilyl-, dimethylmethoxysilyl-, etc. may also be used and do not require a proton scavenger. The order of reactivity of silyl electrophiles is: SiCl > SiOMe > SiOEt. Presence of water in the bonding of di- or trifunctional reagents results in polymerization of the reagent that may or may not covalently bond to silica silanols. Unbonded polymerized reagent may be difficult to wash out and could appear as bleed under certain mobile-phase conditions. The degree of polymer character of phases may be measured by a National Institute of Standards and Technology (NIST) test mix developed by Sander and Wise. The mix is designated as standard reference material (SRM) 869. It contains three polycyclic aromatic hydrocarbons (PAHs): benzo[a]pyrene (3) (BaP) [50-32-8], 1,2,3,4,5,6,7,8-tetrazenonaphthalene (4) (TBN) [34478-91-6]
and phenanthro[3,4-c]phenanthrene (5) (PhPh) [87-83-7]. Level of polymeric C18 bonded phase is measured based on the resulting selectivity and elution order of the PAH components in the SRM 869 mix run on the phase in question.

An end-capping step most often is performed following bonding, to reduce the number of active surface silanols further. The end-capping reagent, being smaller than the bonding reagent, bonds to silanols not accessible to the bonding reagent. Examples of end-capping reagents include trimethylchlorosilane [75-77-4] and hexamethyldisilazane [999-97-3].

Ludwig et al. concluded that bonded-phase ligand density might play a role in hydrolytic stability of the bonded phase. Maximum ligand density or coverage is obtained by using excess bonding reagent and good synthetic technique. Moisture can hydrolyze the reactive bonding reagent and/or polymerize the precursor. Higher coverage also assists in deactivating active silanols. Larger pore size particles (e.g. 200–500 Å) may be more available to bonding reagents than 60–100-Å pore size particles, and may display superior base deactivation due to higher coverage. Larger pores are also preferred for separation of larger molecules such as proteins. Bonded phases with smaller pore sizes have greater surface area, higher percent carbon and longer retention.

3.3 Nonsilica High-performance Liquid Chromatography Phases

Polymeric and other nonsilica HPLC packings avoid active silanols altogether. State-of-the-art polymer particle and pore sizes are controlled with desirable narrow distribution. The pH stability is improved over silica-based packings as shown in Table 3. Polymeric columns still suffer in that they have lower efficiencies than silica-based columns. Polymers also tend to shrink and swell in certain solvents and are not as rigid as silica. For years, researchers have tried to overcome these shortcomings. Progress has been made, but the advantage remains with silica. Silica phases contain at least 10 000 plates m⁻¹ more efficiency than the best polymeric phases in well-packed columns. Polymer phases still shrink and swell to some degree, even with high cross-linking. The major utilities of polymeric phases have taken foundation in applications requiring extreme pH conditions, and in ion exchange, size exclusion and biomolecule separations.

Porous glassy carbon (PGC) phases, such as the commercial product called Hypercarb®, can be run at any pH. The solid support is sp²-hybridized, 100% carbon, formed at high temperatures, with a morphology described as being interwoven ribbon-like strands. Figure 7 depicts how the material is believed to exist as a chromatography medium.

The flat surface of the ribbons acts as the location for certain adsorption processes of the solute. Positional isomers of derivatized phenyl groups, for example, are well discriminated by this adsorption mode of separation. Molecules capable of more contact points with the PGC surface are retained longer than compounds with few contact points as pictured in Figure 8. The o-xylene isomer has four contact points on the PGC surface and is retained the longest. The second longest retained isomer is the p-xylene isomer which has four contact points temporarily on one side (a, b) of the molecule, but that can flip to the other side (c, d). Therefore, there may be times when it has just two points of contact as opposed to constantly having four contact points, as in the case of the ortho isomer. Finally, the meta isomer has just three points of contact with the PGC surface, and elutes first. This elution order is opposite to that seen on conventional C18 phases.

Stereoisomers are also good candidates for PGC phases as outlined by Karlsson and Pettersson, where the flat surface aids in the “three point attachment” model first introduced by Dalgleisch. The discriminating PGC phase was used by Azzoui et al. to analyze
benzodioxinic isomers that could not be separated by normal or reversed-phase HPLC or by GC.

Perhaps the greatest potential for PGC phases is in retaining very polar compounds. Solutes that do not retain on even the most retentive C18 phases should be tried on the PGC phase, which also operates on a reversed-phase mechanism. Solvent strength is very different for PGC than for C18 phases. Acetonitrile and methanol are strong solvents for C18 phases, but are relatively weak for PGC phases. The strength of solvents for PGC phases is solute dependent and not readily definable.

PGC phases have also been prepared at low temperatures, where the degree of glassy carbon formation is controlled. The degree of PGC formation dictates solute selectivity. The higher the process temperature used, the more the phase resembles Hypercarb®. Therefore, desired chromatographic activity can be “tuned” by controlling the temperature of PGC formation.
Low-temperature PGC phases have not been commercialized at the time of this writing.

Zirconia-based HPLC phases have recently entered the market under the tradename, Zirchrom®. The 3-µm zirconia solid support is extremely stable and is operable from pH 0 to 14. Zirconia monomeric bonded phases appear to be significantly less stable than the corresponding silica monomeric phases. However, polymer, PGC and ionic coatings on the zirconia particles are available. Mass transfer appears to be slower on zirconia phases than on silica bonded phases, which is compensated for by running separations as high as 200 °C. The higher temperature conditions also reduce higher backpressures caused by the 3-µm particle by decreasing mobile phase viscosity.

Modified alumina phases have also been reported by Holland et al. Although they are not robust throughout the entire pH range as are PGC and zirconia phases, they are stable from pH 2 to 13, which is an advantage over silica phases. Lingeman and Underberg reviewed undervatized alumina which can be used both as an anion exchanger or a cation exchanger for the analysis of basic and acidic compounds, dependent on the pH of the mobile phase. Selectivity for acidic and neutral compounds was particularly good, although the retention mechanism was rather complex on alumina phases.

3.4 Direct Inject Columns

Considerable cost and sample preparation time savings can be realized using phases designed to handle the direct injection of serum and urine samples for pharmaceutical analysis. Early attempts involved automated column-switching techniques between two columns, which are still used today. The sample plasma or urine sample reaches the first column, where proteins and undesirable molecules are unretained and pass directly to waste. Meanwhile drugs to be analyzed are strongly retained and trapped on the first column. A valve is switched directing a stronger mobile phase to elute (usually by backflushing) the trapped drugs from the first column onto an analytical column and then to a detector. The first column (precolumn) is usually bonded with a diol-containing phase of some sort. This provides a “protein friendly” environment to which proteins will not stick. The second, analytical column must be sufficiently retentive to perform the drug separation under the strong mobile phase conditions needed to elute them off the precolumn. Yu and Westerlund described such a system using an alkyl-diol precolumn and a C₁₈ analytical column for direct plasma analysis of methotrexate [59-05-2]. Clarke and Robinson reviewed several HPLC clean-up procedures, among which was the column-switching technique that gave high drug recovery rates of from 95% to 100%, and with low coefficients of variation. Other acclamations of the practice of this technique for the analysis of drugs in biological samples have been published.

Phases were then developed with the concept of using one column that excludes proteins, but retains small molecules, especially drugs. Such a phase eliminates the need for the more complicated column-switching techniques. Pinkerton and Hagestam were the first to introduce this notion, whereby small molecules were retained in the pores, which were bonded with a glycerylpropyl/glycine-L-phenylalanine-L-phenylalanine (GFF) phase. The outside surface was treated by carboxypeptidase A, which is too large to enter the pores. The external surface, after enzymatic treatment, contained glycerolpropyl glycine chemistry, which occluded protein molecules from entering packing pores. Small solutes were retained in the pores by the GFF phase that survived enzyme treatment. The designation, internal surface reversed phase (ISRP) was given to describe the chemistry. Mohammad and Morrison separated methylene violet biological stain in a DNA-containing sample matrix, on an ISRP GFF column. Perry published an in-depth review of this packing. Shihabi discussed some of the earlier pros and cons associated with ISRPs compared to other direct injection techniques of serums, which are still applicable today.

Other ISRP-like packings have been developed which are modifications of the original to varying degrees. Haginaka summarized several of these phases including semipermeable surface (SPS), dual zone (DZ), shielded hydrophobic phase (SHP) and mixed functional phase (MFP). Collectively, they are known as restricted access phases.

4 MODES OF CHROMATOGRAPHIC SEPARATION

The most widely used modes of pharmaceutical analyses include reversed-phase, normal-phase and ion-exchange chromatography. Mechanisms describe, on the molecular level, how the separations occur.

Reversed-phase separations may take place by partitioning or adsorption mechanisms. Although there is still some debate, it is generally believed that C₁₈ and similar hydrophobic phases retain solutes by their partitioning from the mobile phase into a solvated organic coating on the hydrocarbon stationary phase. Retention of solutes, therefore, is involved in a liquid:liquid partitioning process, as shown in Figure 9.

In contrast, PGC phases are thought to operate by an adsorption mode, which may explain the exceptional
selectivity these phases show for positional and stereoisomers. Figure 8 depicts a PGC hydrophobic surface that molecules interact with directly.

Normal-phase separations also occur either by partitioning or by adsorption. Prevalent thinking associates diol, amino and cyano bonded phases with the partitioning mechanism, whereas bare silica is postulated to act by adsorption.

Ion-exchange mechanisms include WAX, SAX, WCX and SCX, as discussed in section 2.5 and pictured in Figure 9. For ion exchange of acidic compounds, the mobile-phase pH should be at least one unit above the $pK_a$ of the solute ($pK_a$s of carboxylic acids are typically about 5) to deprotonate and ionize the acid. Basic solutes ($pK_a$s of secondary and primary amines are ordinarily about 8 or 9, respectively) require a
mobile-phase pH of at least one unit lower than the pKₐ of the analyte to protonate the species. A strong mobile-phase solvent is favored to reduce secondary modes of separation from transpiring. Elution of target solutes from the stationary phase ensues by mobile-phase additive ions displacing them from the ionic stationary phase. Gradients of increasing buffer concentration are typical, although isocratic ion-exchange separations are not uncommon. In practice, few separations are purely ion exchange, but also contain, for example, some secondary partitioning.

5 PHASE SELECTION BY ANALYTE FUNCTIONAL GROUP TYPE

5.1 Acids

Low-molecular-weight or polar acids are difficult to retain by reversed-phase columns. Retention of acids increases, while bases decrease, with lower pH mobile phases. Correspondingly, acids are less soluble and bases are more soluble in aqueous mobile phases at lower pH. Obviously, there are other factors that also contribute to reversed-phase retention. Most polar acid separations, therefore, are conducted at low pH to gain retention. However, peak broadening occurs when the analyte solubility in the acidic mobile phase becomes a significant issue.

To retain the most polar acid samples, earlier HPLC methods resorted to complex mobile phases with ion pairing agents on active, Type A, silica C₁₈ packings. For example, Honnegger et al. separated ascorbic acid [50-81-7] and uric acid [69-93-2] from tissue extract using an acidic mobile phase becomes a significant issue.

5 PHASE SELECTION BY ANALYTE FUNCTIONAL GROUP TYPE

5.1 Acids

Low-molecular-weight or polar acids are difficult to retain by reversed-phase columns. Retention of acids increases, while bases decrease, with lower pH mobile phases. Correspondingly, acids are less soluble and bases are more soluble in aqueous mobile phases at lower pH. Obviously, there are other factors that also contribute to reversed-phase retention. Most polar acid separations, therefore, are conducted at low pH to gain retention. However, peak broadening occurs when the analyte solubility in the acidic mobile phase becomes a significant issue.

To retain the most polar acid samples, earlier HPLC methods resorted to complex mobile phases with ion pairing agents on active, type A, silica C₁₈ packings. For example, Honnegger et al. separated ascorbic acid [50-81-7] and uric acid [69-93-2] from tissue extract using an active packing and a pH 3.5 mobile phase consisting of phosphate buffer, EDTA (ethylenediaminetetraacetic acid), and sodium octylsulfate. Methods of such enhanced complexity are difficult to reproduce.

Chang et al. employed normal-phase amine and β-cyclodextrin (CD) columns to separate substituted benzoic acids under simpler mobile-phase conditions using acetic acid, isopropyl alcohol and methanol. Similarly, Mallet et al. analyzed dihydroxyeicosatetraenoic acids by normal phase on bare silica using hexane, isopropanol, methanol and acetic acid as mobile phase. Separation by GC required derivatization to the corresponding -butyldimethylsilyl or -butylmethoxyphenylsilyl esters. However, normal-phase methods are generally not as robust as reversed-phase methods.

Acids separations may be performed on SAX or WAX columns. Under ion-exchange conditions, the mobile phase pH is adjusted to at least one unit higher than the pKₐ of the solute to ionize the acid. As noted in section 2.5, WAX columns must also be used with a mobile-phase pH that is at least one unit below the pKₐ of the bonded amine moiety. These two necessary conditions customarily place the working range of WAX columns at about pH 6–7.5. Silica-based SAX columns are also limited to approximately the same pH range, since higher pH mobile phases may hydrolyze the silica backbone. Xia and Gilmer successfully retained the highly polar sialic acid [131-48-6] using a SAX column. Polymer-based SAX columns may be operated at higher pHs. Schmucker and Bulusu et al. include reviews of some earlier ion-exchange separations of acids.

More recent developments in HPLC column technology seek to perform separations of polar acids by novel reversed-phase packings that provide more robust methods than nonreversed-phase modes of separation. Among these phases are the aforementioned IBD and high aqueous reversed-phase packings (see section 2.5). In another approach, Tischer and Cardellina used a polybutyldiene-coated alumina phase to separate tri-terpen carboxylic acids without the need for any ion pairing, ion suppressing or buffering additives.

Acids of moderate to low polarity are relatively easy to separate on either Type A or Type B hydrocarbon phases. Abscisic acid [14375-45-2] and indol-3-ylacetic acid [87-51-4] contain sufficient hydrophobicity to be retained by conventional reversed-phase C₁₈ packings. Kwong surveyed a variety of ways that the moderately polar acetylsalicylic acid (aspirin) [50-78-2] and its metabolites can be separated, including the use of C₁₈ phases. More hydrophobic solutes, such as the fatty acid γ-linolenic acid [463-40-1], can be converted to esters for reversed-phase C₁₈ or for polyethylene glycol phase GC separation. However, derivatization often is not necessary for HPLC fatty acid separations. The type of sample preparation for GC or LC (liquid chromatography) separations of pharmaceutically important organic acids depends largely on analytical objectives, as outlined by Liebi et al. Mukherjee and Barnes reviewed carboxylic acid derivatization reagents for HPLC, if the situation so warrants the additional effort required for this sample preparation.

Phenols should be recognized as weak acids owing to the acidic nature of the phenolic proton. Thomassin et al. reported successful separations of several p-hydroxybenzoic esters and p-hydroxybenzoic acids on a standard C₁₈ packing (also, see parabens in section 6.24). Cabaleiro and Cela employed an active C₁₈ column and protonated both stationary-phase silanols and the polyphenolic solutes with 1% acetic acid in the methanol and acetonitrile mobile-phase gradients. Polyphenolic acid retention on a PGC is dependent on the aromatic ring substitution, as documented by Vazquez et al.
5.2 Bases
Tailing of basic solutes on silica HPLC packings is commonly rationalized by analyte interaction with surface silanols (see section 3.2). Tetraalkyl ammonium ions, sometimes referred to as ion suppressing agents, mask active surface silanols, greatly improving peak shape for basic solutes. Such additives were particularly important in earlier separation techniques before type B silica packings became available. Even with type B silica phases, improvements may be seen with ion suppressing agents. Peak shape can also be improved by using acidic mobile phases that protonate silica siloxides. This may be undesirable for polar basic compounds since lower pH generally elutes bases faster than when the pH is neutral. Good base deactivated phases offer a clear advantage in such situations.

Normal-phase separations of basic compounds on bare silica and alumina were reviewed by Lingeman and Underberg. Additional base solute separations are listed in section 6.

5.3 Acid/Base Mixtures
Mobile-phase conditions optimized for acids may not be favorable for bases and vice versa. Conventional packings do not handle a mixture of both kinds very successfully. Problems with retention and peak shape of one or both solute types are commonplace, even with all but the most base deactivated, type B phases. On C18 phases, bases decrease in retention and sharpen in peak shape, while acids decrease in retention and broaden in peak shape with decreasing pH (for example, see results published by Das-Gupa and Mathew). One of the advantages of IBD phases is that they show excellent peak shape for acid/base mixtures for a wide pH range and have complementary selectivity to C18 phases. However, highly base deactivated C18 phases are more predictive of retention characteristics and separate most mixtures encountered by analysts. Mutton claimed that one phase type successfully separated 95% of 1250 acid and base pharmaceutical candidates synthesized in the preceding year.

For methods development of acids and bases on reversed-phase columns, Zhu et al. recommend starting by varying the gradient steepness and beginning at low pH. If the variation of these two parameters does not achieve the desired selectivity, the effect of temperature should then be explored. Snyder estimated relative contributions of temperature, solvent strength, column type and solvent type towards selectivity and weighted these factors against the ease of operation in changing them. Varying percent organic in the mobile phase, temperature and solvent type (methanol or acetonitrile) was advocated first. If ineffectual, solvent type (methanol, acetonitrile or tetrahydrofuran), column type, pH and/or ion pair reagent concentration deviations should be tried next.

5.4 Zwitterions
Because they contain both acid and base functionality on the same molecule, zwitterionic solutes can sometimes pose challenging problems in obtaining good peak shape and retention. As might be expected, IBD phases have excellent peak shape for zwitterionic compounds, in addition to acids and bases. Stationary phases of multimode separation ability have been prepared by immobilizing a zwitterionic molecule onto silica particles. Yu et al. bonded glutamic acid to silica and were able to separate acids and bases simultaneously, including nucleosides. Chou and Yang simultaneously ran acids, bases and amino acids on an immobilized zwitterionic stationary phase. Yang et al. invoked a similar “like-retains-like” strategy in preparing two other zwitterionic stationary phases.

5.5 Polar Compounds
Retention of polar ionic solutes is discussed in sections 5.1 through 5.4. As with those solutes, methods development of nonionic polar analytes is best performed under reversed-phase conditions, if possible. Newer high aqueous reversed-phase columns and IBD phases (section 2.5) are ideal for extra retention accrual.

5.6 Halogenated Compounds
HPLC stationary phases have been developed that provide exceptional selectivity for pharmaceutical compounds containing halogen atoms. Perhaps conceived by a “like-retains-like” strategy, these stationary phases contain halogenated groups themselves. The most popular halogen for this purpose is the fluorine atom, possibly because of its strong electronegative nature. One of the more common commercially available fluorinated packings is known as Fluofix®, a partially fluorinated branched hydrocarbon stationary phase (Figure 10).

Maisch depicted several advantages of this phase. The fluorinated packing separated fluorinated adrenocortical hormones and the epimers 3-β-panaxadiol [1966-76-3] and 3-α-panaxadiol, which could not be resolved on traditional C18 phases. It appears to show good selectivity for positional and cis/trans isomers as well. Jinno and

Figure 10 Fluorinated Fluofix® stationary phase.
Nakamura\(^{(96)}\) attributed the special selectivity of polar solutes to the larger polarity of the fluorinated phase compared to C\(_{18}\) phases. Aboul-Enein and Serignese\(^{(97)}\) accomplished the separation of taxol A \([33069-62-4]\) and five of its derivatives using a Fluofix\textsuperscript{®} column.

Taxol and related compounds have also been separated on a pentfluorophenyl (PFP) phase.\(^{(98)}\) Another PFP phase, a heptadecafluorododecyl phase and a 3-(heptafluorosopropoxy)propyltrimethylsilane phase exhibited marked retention differences compared to C\(_{18}\) phases, affected by different solute functional groups.\(^{(99)}\)

Krafft et al.\(^{(100)}\) credited the greater transfer energies of the CF\(_2\) over the CH\(_2\) groups with achieving longer retention and better separation of a series of perfluoroalkylated compounds on two perfluoroalkylamino stationary phases compared to a C\(_{18}\) phase. Rectilinear plots of capacity factor versus number of carbon atoms were obtained. Also, utility was found for fluorinated stationary phases in the analysis of fluorinated surfactants,\(^{(100)}\) flavonoids and fluorinated phenols,\(^{(101)}\) and for high recovery rates of proteins.\(^{(102)}\) Similar to silica-based fluorinated bonded phases, Hirayama et al.\(^{(103)}\) discovered that a perfluoroalkyl acrylate phase provided more efficient separation of fluorne-containing compounds than a C\(_{18}\) packing. It is noteworthy that one nonfluorinated phase, poly(vinyl p-t-butylbenzoate), also showed preferential retention of halogenated solutes compared to C\(_{18}\) silica, polystyrene/divinylbenzene and poly(methyl methacrylate–ethyl dimethacrylate) phases.\(^{(104)}\)

Dhanesar and Poole\(^{(105)}\) compared GC fluorinated phases to nonfluorinated phases in separating some halogenated solutes. Organic compound retention was determined to be about 2–6 times less on the fluorinated versus nonfluorinated stationary phases of similar polarity.

Fluorinated phases are not the only phases suitable for halogenated compound separations. Conventional C\(_{18}\) packings often are sufficient. For example, 5-fluoro-2'-deoxycytidine \([10356-76-0]\) and 5-trifluoromethyl-2'-deoxycytidine \([66384-66-5]\) were detected on a C\(_{18}\) phase by Briggle et al.\(^{(106)}\) Leone and Collins\(^{(107)}\) employed simple isocratic mobile phases in separating nine simple perhalogenated compounds on C\(_{18}\) phases. Interpolation curves of log mass distribution ratios versus number of solute chlorine atoms accurately predicted observed retention time.\(^{(108)}\) Yamaguchi and Hanai\(^{(109)}\) compared high versus low carbon load and end-capped versus nonend-capped C\(_{18}\) phases for solutes including some halogenated phenols. They concluded that the low carbon load, nonend-capped C\(_{18}\) phases gave superior selectivity, but suffered from short column lifetime. De Vries and Rekker\(^{(110)}\) separated halogen-substituted aromatic compounds on bare silica and alumina packings under normal-phase conditions. Retention was significantly affected by the substitution pattern of the aromatic solutes and by the bulk and mobility of the mobile-phase molecules.

Documented GC analysis of halogenated pharmaceuticals, as with nonhalogenated pharmaceuticals, is far less prevalent in recent literature than is HPLC analysis publications. GC analysis finds usefulness with more volatile compounds in pharmaceutical analysis, such as drug headspace analysis,\(^{(111)}\) urinary halogenated hydrocarbon degradation products in drugs of abuse screening,\(^{(112)}\) and analysis of the highly volatile anesthetic, halothane.\(^{(113)}\) Some organohalogen drugs in legal medicine analysis by GC/MS were summarized by Suzuki et al.\(^{(114)}\)

### 5.7 Chiral Compounds

Drug candidates containing a chiral center(s) present a unique challenge to the analytical chemist. Racemic compounds, differing only by the arrangement of atoms in space, represent the most challenging of all mixtures to separate. Isolation of the individual enantiomers is very important for evaluation of their respective biological activity and toxicity, which may be quite different. For example, Silber et al.\(^{(115)}\) reported that the (S)-isomer of propranolol is 100 times more potent as a \(\beta\)-blocker than the (R)-isomer. In extreme cases, racemic drugs may be considered to be only 50% pure owing to the presence of the inactive enantiomer. Krstulovic\(^{(116)}\) summarized some complex activity, toxicity and pharmacokinetic scenarios possible with racemic drugs. Although the US FDA does not currently require it, potential biological activity differences associated with stereoisomers make it prudent for pharmaceutical companies to determine each enantiomer’s individual activity and toxicity. Chromatographic resolution of enantiomers has rapidly expanded as a result. This work mainly involves three processes for chromatographic separation of racemic mixtures, in using chiral stationary phases (CSPs), chiral mobile phase additives (CMPAs) and a CSP and CMPA simultaneously.

Choice of CSPs largely remains empirical at the time of this writing. The best approach is to choose a column that is known to separate racemates of similar structure, and/or meets the general requirements outlined in the literature for successful chiral recognition of the CSP for the solute. Trace analysis of enantiomers may benefit from having the option to choose between a (R)-CSP and the corresponding (S)-CSP. It is generally desirable to have the minor enantiomer elute before the major enantiomer, so that the latter does not tail into the former, in closely eluting peaks. If, for example, a (R)-CSP elutes the minor enantiomer last, then switching to the opposite (S)-CSP will reverse the elution order, as desired, without changing any other chromatographic conditions.
In chiral separations where mixtures contain overlapping metabolic peaks, two or more columns with different selectivities may be used to effect separation. For example, Fried and Wainer\(^{117}\) used a diol silica precolumn to perform an achiral separation of verapamil [52-53-9]/verapamil metabolites and norverapamil [67812-42-4]/norverapamil metabolites, which was then coupled to a chiral column for enantiomer separation. Without the initial achiral separation, overlap of nonenantiomeric peaks was problematic. Ducharme et al.\(^{118}\) commented that chiral methods validation ideally should be conducted on each enantiomer and the racemate, in order to document the amount of interference between the enantiomers, if any. Figure 11 exemplifies one possible interference, where Fujima et al.\(^{119}\) recorded racemization of lorazepam [846-49-1] at 25°C. The baseline rise between eluting enantiomer peaks is indicative of racemization and the method should be modified to avoid this problem.

Chromatographic separations of enantiomers was initiated in 1952 by Dalgleish\(^{46}\) in his “three point interaction” model depicting the stereogeometric interaction of racemic solutes with a single-enantiomer stationary phase. (Biochemists may readily associate the analogy

![Figure 11](image-url)

**Figure 11** Temperature-dependent racemization of lorazepam enantiomers on an ovomucoid (OVM) chiral column. Column temperature: 7°C (a), 10°C (b), 15°C (c) and 25°C (d). (Reprinted from H. Fujima et al.\(^{119}\) *J. Liq. Chromatogr.*, 16(4), 879–891, 1993, by courtesy of Marcel Dekker, Inc.)
of this model to the Ogsten, “three point landing” model(120) diagramming stereochemical interactions of active biomolecules with enzymes/proteins). The model involves interactions between three groups bonded to the chiral center on the analyte with three groups on the CSP, as displayed in Figure 12. Solute enantiomer a has a more favorable “fit” to the stationary phase regarding attractive interactions than does solute enantiomer b. Therefore, a is retained longer than b. It is important to note that not all three interactions need to be attractive interactions. Steric hindrance and charge:charge repulsions may also contribute.

Some of the earliest commercially available chiral HPLC phases were the so-called “brush type” or “pirkle” phases, the latter of which was named after the inventor. One of the three points of interaction which is a characteristic of pirkle phases is \( \pi : \pi \) attraction. The CSP dinitrobenzoylphenylglycine (DNBPG) molecule in Figure 13 has electron-withdrawing groups on the aromatic ring that produce an electron-deficient or \( \pi \)-acidic phenyl ring. This CSP is designed for solutes containing an electron-rich or \( \pi \)-basic aromatic ring. This structural “requirement” can be met for primary and secondary amine analytes by derivatization with, for example, benzoyl chloride or naphthoyl chloride.

For \( \pi \)-acid solutes, CSPs containing \( \pi \)-base phases are commercially available, such as the naphthylethylurea CSP displayed in Figure 14. With this phase, a suitable derivatization reagent for primary and secondary amines might be 3,5-dinitrobenzoylchloride.

Many commercial brush-type phases have been developed over the years, with varying degrees of success. In general, they do not demonstrate a broad range of applicability without solute derivatization.

The spectrum of underivatized compounds capable of being separated on one particular phase increased with the advent of CD phases. Commercial CD phases are currently available for both HPLC and GC separations. The three most prominent phases, \( \alpha \)-, \( \beta \)-, and \( \gamma \)-CD, contain 6, 7, and 8 glucopyranose rings, respectively, hooked by 1,4-linkages as shown in Figure 15. The respective cavity sizes are 4.5 Å, 6 Å and 8 Å in diameter.

Retention may occur by either inclusion of a hydrophobic portion of the analyte into the cavity or by “capping” the top of the CD cavity. Hydroxy groups at the mouth of the CD molecule are available for hydrogen bonding as part of the discrimination process, which is especially important for enantiomers, and also to some extent in separations of structural and geometric isomers. Commercial permethylated CD columns are also available, and appear to separate an even broader range of racemates than unmodified CD phases. They should be tried first, unless the analyte contains hydroxy functionality, which underivatized CD phases may better recognize through hydrogen bonding.
Immobilized proteins (affinity phases) are fairly versatile in separating a wide range of underivatized chiral solutes. They take advantage of the natural chiral recognition processes of biological systems. Commercial columns include bovine serum albumin (BSA), human serum albumin (HSA), OVM, \(a_1\)-glycoprotein (AGP) and other phases. The proteins are usually covalently bonded to a 300-Å silica support, which contains a large enough pore size to incorporate the protein. Among the serum albumin phases, it is interesting to note that, although there is a high homology between the various sources (bovine, human, sheep, pig, etc.), Tittelbach and Gilpin\(^{122}\) found that small differences in the amino acid sequence can have a pronounced effect on solute selectivity. Lower column temperatures often increase resolution, presumably by freezing protein conformation, thereby improving enantiomer recognition. Some drawbacks of protein phases include slower mass transfer characteristics causing peak broadening and mobile-phase restrictions that are recommended by column manufacturers to avoid denaturing the protein.

Derivatized cellulose CSPs provide a broad range of separations as summarized by Aboul-Enein and Islam.\(^{123}\) With the exception of triacetyl and tribenzoylcellulose, derivatized cellulose phases are largely covered by patents owned by Daicel Chemical Industries Ltd., Tokyo, Japan.

Chiral ligand exchange chromatography (CLEC) was introduced by Davankov\(^{124,125}\) in 1970. Amino acid racemates may be separated without derivatization, using the CLEC phase, which incorporates an immobilized single enantiomer amino acid. The amine and carboxylate functional groups complex with a metal ion, such as copper, which in turn complexes with the amino acid solutes. The solute enantiomer that forms the most stable complex is retained longer, giving rise to the separation process. Disadvantages of this technology include long equilibration times associated with the metal-containing complex mobile phase, and that the technology is not compatible with MS (mass spectrometry) detection.

Chiral crown ether phases embody cavities involved in the separation of racemic mixtures containing primary amines. Sousa et al.\(^{126}\) first introduced these phases, which were later modified for free amino acid racemate separations.\(^{127}\) Secondary and tertiary amines do not separate on these phases, which limits their usefulness. However, Hilton and Armstrong\(^{128}\) have successfully separated dipeptides.

Chiral imprinted gels are very specific for a targeted racemic mixture. A solute enantiomer is used as a template, bound in a cross-linked polymer. The template molecule is then removed by hydrolysis, leaving a cavity that retains the identical enantiomer or one with very similar structure.

Another application-specific chiral phase was developed for racemic barbiturates, hydantoin and glutarimides by Feibush et al.\(^{129}\) The phase contains functionality strategically located to form triple hydrogen bonds with the solutes, similar to biochemical base pair formation.

A more recent development of CSP technology is the macrocyclic chiral phases published by Szczepaniak and Szymanski,\(^{130}\) and then expanded upon by Armstrong et al.\(^{131}\) Molecular cavities, reminiscent of crown ether and CD cavities, but larger and of different chemistry, are thought to be involved in the separation process. The number and types of racemate that are separable is reported to be greater than any other single chiral phase, although the reproducibility of the commercial phase may prove to be difficult to control. Among the most popular covalently bonded macrocyclic chiral phases are vancomycin\(^{[123490-00-7]}\) for N-protected amino acids and drugs\(^{131}\) including warfarin\([81-81-2]\)\(^{,132}\) teicoplanin\([61036-62-2]\)\(^{,133}\) for protected amino acids\(^{134}\) and underivatized amino acids, peptides, \(\alpha\)-hydroxy carboxylic acids, cyclic amides and amines,\(^{133}\) and ristocetin A\([1404-55-3]\) for derivatized or underivatized primary and secondary amino acids and di- and tripeptides.\(^{134}\)

CMPAs can be used in conjunction with a standard C\(_{18}\) or other reversed-phase column. Here, the recognition occurs by the complexing of the CMPA with each of the enantiomers. The complex formation results in two pseudodiastereomers, which nonchiral phases are capable of discriminating between.

Chiral separations can be predictably improved by using both a CSP and a structurally homologous CMPA in concert. Somewhat surprisingly, the beneficial CMPA (of opposite stereochemistry to the CSP) does not elute the less retained solute enantiomer from the column relatively faster than the other solute enantiomer, but rather performs a proposed stereoselective “salting out” process. The longer retained solute isomer, hypothetically, is forced to reside longer on the bonded phase by being salted out of the mobile phase. Therefore, enhanced CSP/CMPA enantiomer separations occur solely due to the more retained enantiomer, while the less retained enantiomer is not affected in a chiral recognition sense. Duff et al.\(^{135}\) proposed a “push/pull” model to describe this process, as shown in Figure 16.

6 PHASE SELECTION BY ANALYTE CLASS

6.1 Adrenergic

Pharmaceutical separations of adrenergic \(\beta\)-blockers can be accomplished on ordinary C\(_{18}\) phases. Maguregui et al.\(^{136}\) analyzed urinary alpranolol [13655-52-2],...
Figure 16 Push/pull model for CSP/CMPA synergism. (Reproduced from K. Duff et al. Chirality, 5, 201–206. Copyright 1993, with permission from Wiley-Liss, a subsidiary of John Wiley & Sons.)

Figure 17 GC Separation of racemic ibuprofen. 30 m, 0.32-mm ID, 0.25 m Rt-βDEXsm, on column injection, concentration approximately 125 ng each enantiomer; oven temperature 175–200 °C at 2 °C min\(^{-1}\), injection/det. temperature 200 °C/230 °C; carrier gas, helium at 60 cm s\(^{-1}\); detector type, GC/FID; split ratio 13:1 using cup splitter sleeve. (From Restek Corporation with permission.)

at enolol [29122-68-7], metoprolol [37350-58-6], nadolol [42200-33-9], oxprenolol [6452-71-7] and timolol [26839-75-8] at the parts-per-billion level using a common C\(_{18}\) column and electrochemical detection. Pindolol [13528-86-9] in urine and plasma was determined by Ohta et al.\(^ {137}\) using a column-switching technique (see section 3.4), with the second column (the analytical column) being a C\(_{18}\) phase. It is important to note that lower wavelengths of about 230 nm should be used for many β-blockers in order to detect them by UV absorbance.

Chiral separations for racemic atenolol, bevantolol [59170-23-9], celiprolol [56980-93-9], metipranolol [22664-55-7], metoprolol, oxprenolol, pindolol, propranolol and sotalol [3930-20-9] were accomplished by Ceccato et al.\(^ {138}\) on an AGP phase (see section 5.7). Attempted chiral resolutions of 18 β-blockers were conducted on a newer generation pirkle phase and compared to separations on a cellulose phase (see section 5.7).\(^ {139}\) Toyo’oka et al.\(^ {140}\) obtained low levels of detection of ten racemic β-blockers by derivatization with a chiral fluorescent reagent, followed by HPLC analysis of the resulting diastereomers on a C\(_{18}\) phase.

Although they are not nearly as well documented in the literature, chiral β-blocker separations can also be directed by GC CD phases, as demonstrated in Figure 17.\(^ {141}\)

6.2 Alkaloids

Isoquinoline [119-65-3] and other alkaloids are best separated by HPLC. The choice of separation mode
varies with the sample matrix type. For example, alkaloids in poppy extracts are preferably separated by ion pair chromatography on an aminoethyl phase, while those in biological liquids may primarily be separated by ion-exchange or reversed-phase chromatography.\(^\text{(142)}\) Metabolites of alkaloids are separable from their parent compounds by HPLC.\(^\text{(143)}\) Review articles on alkaloid analyses have been published by Kabulov et al.\(^\text{(144)}\) Papadoyannis\(^\text{(145)}\) and Valka.\(^\text{(146)}\)

### 6.3 Amino Acids

Earlier amino acid separations (also see section 5.4) were run by methods using dedicated cation-exchange columns such as outlined by Walker and Mills.\(^\text{(147)}\) Post-column derivatization with, for instance, ninhydrin was common to improve detection. A large variety of precolumn derivatization reagents gradually emerged for the analysis of amino acids. Review articles can be found for \(\alpha\)-phthalaldehyde,\(^\text{(149)}\) dabsyl chloride,\(^\text{(150)}\) phenylisothiocyanate,\(^\text{(151)}\) and fluorenylmethyl chloroformate.\(^\text{(152)}\) Selective derivatization reagents, for example benzoin for arginine [74-79-3] and glyoxal for tryptophan [54-12-6], are reviewed by Cui et al.\(^\text{(153)}\) The derivatized amino acids can conveniently be run on reversed-phase columns.

### 6.4 Antibacterial/Antifungal

Watanabe et al.\(^\text{(154)}\) analyzed methylated oryzalides and oryzalic acid rice extracts containing antibacterial activity by GC/MS. The derivatized terpenes were separated on a methyl silicone GC column and detected by selective ion monitoring. Fluconazole [86386-73-4] in human plasma was analyzed by Beijnen et al.\(^\text{(155)}\) on a HP-1 GC phase. Other GC methods require modification of the analyte, such as derivatization of plasma canellar [66550-09-2] with bis(trimethylsilyl)trifluoroacetamide of the analyte, such as derivatization of plasma canellar. Saponified steroidal lanosterol [79-63-0] isomers were derivatized by Howell and Mallet\(^\text{(157)}\) to the corresponding trimethylsilyl or \(t\)-butyldimethylsilyl ethers before isolation on a SE-30 column.

Antifungal agents are more prevalently separated on reversed-phase HPLC columns. A cyclic hexapeptide antifungal agent was separated from plasma or urine on a conventional \(C_8\) column by Schwartz et al.\(^\text{(158)}\) Zornes and Stratford\(^\text{(159)}\) used the same type of \(C_8\) phase to assay a lipopeptide antifungal agent in plasma. Another reversed-phase column, this time a \(C_{18}\) phase, was employed by Chung and Paik\(^\text{(160)}\) in discovering the presence of the antifungal active alkaloid ingredient, berberine [2086-83-1], in Japanese quince. Other examples of antifungal separations on conventional reversed-phase HPLC columns include fluconazole,\(^\text{(161,162)}\) nystatin [1400-61-9],\(^\text{(163)}\) heptaenes,\(^\text{(164)}\) the nonapeptides, herbicin A [74188-23-1] and B [74188-24-2],\(^\text{(165)}\) and bromosalicylchloranilide [3679-64-9].\(^\text{(166)}\) Both reversed-phase and normal-phase columns were used by Bergeron et al.\(^\text{(167)}\) in isolating antifungal polyphenols from milkwort plants. Albet et al.\(^\text{(168)}\) used a cyanoprop phase to analyze the imidazole antifungal, sertaconazole nitrate [99592-39-9], which provided excellent separation of the target from impurities. Stopher and Gage\(^\text{(169)}\) used a SEC column to elute directly injected plasma proteins, while trapping voriconazole on a \(C_{18}\) guard column. HPLC separation was then conducted on a 250 x 4.6-mm \(C_{18}\) phase. A less conventional \(\beta\)-CD column was successfully employed by Kim and Lin\(^\text{(170)}\) in analyzing a triazole drug in human plasma. Reviews of antifungal analyses have been published by Woestenbohrs and Heykants,\(^\text{(171)}\) Ristuccia\(^\text{(172)}\) and Warming et al.\(^\text{(173)}\)

### 6.5 Anti-inflammatory

Anti-inflammatory (also see section 6.30) drug analyses are largely accomplished by reversed-phase chromatography. Review articles covering methods through the 1980s include those written by Van Overbeke et al.,\(^\text{(174)}\) Bojarski,\(^\text{(175)}\) McElney\(^\text{(176)}\) and Wilson.\(^\text{(177)}\) The former two referrals specifically cover enantiomer separations. Ho and Chen\(^\text{(178)}\) have summarized some analytical methods.

### 6.6 Antipsychotic

A novel basic antipsychotic agent (also see section 6.9) and its N-oxide metabolites in plasma were analyzed using a \(C_{18}\) phase and an ion pairing reagent.\(^\text{(179)}\) Reversed-phase HPLC has also been suggested as a possible diagnostic tool for postpartum psychosis.\(^\text{(180)}\) Psychotic subjects showed a different pattern of compounds in their cerebral spinal fluid in comparison to normal subjects.

### 6.7 Anthracene Derivatives

Van den Berg and Labadie\(^\text{(181)}\) separated several structurally similar cathartic (purgative) agents on an active \(C_{18}\) phase. Excellent separation was obtained for the anthracene-like compounds chrysophanol [481-74-3], physcion [521-61-9], emodin [518-82-1], aloe emodin [481-72-1] and rhein [478-43-3]. A custom copper(II)phthalocyanine sulfonylaminopropyl silica phase was found to separate electron-rich anthracene and other compounds by Saito et al.\(^\text{(182)}\) Anthracene moieties are also used as fluorophore derivatization agents, such as that described by Goto et al.\(^\text{(183)}\) for 3-oxo-bile acids.

### 6.8 Barbbiturates

(See section 6.17.)
6.9 Benzazepines/Benzodiazepines

Benzazepines and benzodiazepines are sufficiently lipophilic that they are often analyzed on a C₈ (184–189) or phenyl (190) phase instead of a C₁₈ phase. D PST/PST phases dominate in the literature (191–210). Bare silica, cyano and amino normal-phase columns have also been used for several benzodiazepines containing hydrogen bond donor or acceptor groups. (211) Radwanska et al. (212) studied dibenzazepines' interaction with melanin by analyzing the drugs on a melanin-bound aminopropyl silica phase and hydrophobicities were determined on an immobilized artificial membrane (IAM) phase. The chemistry of the IAM phase is designed to mimic cell membranes, as outlined by Alvarez et al. (213)

Benzazepines and benzodiazepines may exist in two twist boat conformational forms, a cup-shaped syn form and an extended anti form. (214) These “frozen” conformations may be visualized by proton NMR, and conformer adsorption coalescence can be obtained by heating the NMR sample. It is interesting to note that Fellegvari et al. (215) documented the ability to study benzodiazepine conformation interconversions, also by HPLC.

Benzodiazepine positional isomers were separated by Jin et al. (216) on a C₁₈ phase. Franzelius and Besserer (217) separated diastereomeric isomers using a β-CD column (see section 5.7). Enantiomeric separations were accomplished on cellulose CSPs (see section 5.7) without the need for derivatization. (218) Some benzodiazepine enantiomers, specifically related to the 3-chiral position, were separated by Nishikawa et al. (219) and Fitos et al. (220) Separations related to the 5-chiral position are also reported. (220, 221)

This class of analytes is somewhat unique among the pharmaceuticals in that, in addition to the many HPLC methods, there are also numerous GC separations appearing in the literature. Most methods are performed by GC/MS and use a variety of columns including SPB-5, (222) DB-1, (223) DB-5 (224) and a 5% phenylmethylsilicone phase. (225) Methods for urinary samples, (223, 224, 226–231) blood/plasma samples, (222, 225, 232–236) and tissue samples are reported. (239) Noninvasive analyses have been gaining emphasis and forensic science has made advancements in technology, reflected by the development of analyses of benzodiazepine in human hair (240–242) and sweat. (243)

6.10 β-Blockers

(See section 6.1.)

6.11 Blood Volatiles

Typically, determination of blood volatiles is conducted by GC/MS using headspace analysis. Blood level ethanol [64-17-5] and other volatiles in drunk drivers were measured by Schuberth (244) on a DB-WAX phase coated with polyethylene glycol. Isovaleraldehyde [590-86-3] in plasma from hepatic encephalopathy subjects was separated on a polyoxyethylene glycol phase by Al Mardini et al. (245) Dunn et al. (246) examined N-nitrosamines in blood using a carbowax column. Other volatiles analyzed in blood include organic pollutants (247–254) halocarbons (255–257) anesthetics (258–261) multiple drugs taken by a suicide subject. (262) mercury [7439-97-6] (following ethylation derivatization). (263) blood cell membrane peroxidation residues, (264) solvent thinner (265) and EDTA[60-00-4] (following esterification). (266)

HPLC analysis of blood volatiles generally requires derivatization. For example, Vollmer et al. (267) derivatized ethylene glycol [107-21-1] with benzoyl chloride before HPLC separation on a C₁₈ column. However, literature applications are largely of GC, not HPLC methodology.

6.12 Cardiovascular

Cardiovascular agents containing basic moieties are best separated on type B silica reversed-phase packings. Nevertheless, many literature methods include type A reversed-phase separations. Using the more active type A silica requires ion-pairing and/or ion-suppressing reagents to be added to the mobile phase. Bonazzi et al. (268) used an active C₁₈ phase to determine the angiotensin-converting enzyme (ACE) inhibitors, ramipril [87333-19-5], quinapril [85441-61-8], benazepril [86541-75-5], lisinopril [83915-83-7] and enalapril [75847-73-3]. Even with sodium heptanesulfonate mobile-phase additive, a low pH (2.5) was required to avoid peak splitting and band broadening. The more complex mobile phases were also needed for similar cardiovascular separations on type A packings. (269–272) Normal-phase bare silica columns have been used for cardiovascular separations, both with water (273) and without water (274) in the mobile phase. Review articles on the HPLC separation of eicosanoids (275) and GC analysis of lipoprotein (a) (159577-00-1) and homocysteine [454-29-5] for risk factor studies of cardiovascular disorders (276) have been published.

Chiral separations of cardiovascular drugs include pindolol on an AGP affinity column, (277, 278) and several brush-type phases were compared for a series of basic solutes. (279)

6.13 Catecholamines/Phenols

The HPLC analysis of catecholamines (also see section 6.24) has grown since the 1970s and is presently the major method of analysis. Cation-exchange columns are used under acidic conditions, where the amine functionality of the catecholamine is essentially completely
protonated. Newer type B reversed-phase columns often give excellent peak shape and selectivity and are a good first choice phase for methods development. The reader is referred to several review articles for HPLC separations. Analysis by GC/MS is also popular and is reviewed in the literature.

Phenolic compounds are weak acids and may be separated by anion-exchange columns as previously discussed (see section 5.1). Simple reversed-phase packings are a preferred alternative. Bosch et al. documented a review of phenolic compound separations.

6.14 Cephalosporins/Penicillins

Cephalosporins/penicillins are relatively labile compounds, subject to acid and, especially, base hydrolysis. Care should be exercised in choosing a pH at least one unit away from the pKₐ of the solute. Penicillins are generally strong organic acids, with pKₐ values less than 3. Therefore, HPLC separations most often are run at pH 4.5–7.5. Tailing, chiefly at neutral pH mobile phases. Before type B reversed-phase packings often show unacceptable peak tails, chiefly at neutral pH mobile phases. Before type B packings became available, methods using active C₁₈ and other reversed-phases resorted to ion-pairing or ion-suppressing mobile-phase additives. A method for metronidazole analysis by Venkateshwaran and Stewart demonstrates that a type B reversed phase can be used with simpler mobile phases (phosphate buffer and methanol in this case). The IBD phases are particularly valuable for analyzing this class of compound yielding excellent peak shape and selectivity even under neutral pH conditions.

Elevated temperatures accelerate decomposition. Because of the lack of thermal stability, GC methods for cephalosporins/penicillins are few.

6.15 Cold Medicines

Cold medicine ingredients are relatively easily separated with good peak shape on type B silica reversed-phase packings. Caffeine is often used in reversed-phase test mixes as a control for testing the level of base deactivation of packings. It maintains fairly sharp peak shape even with the more active phases, whereas other basic compounds may interact with the silanols so strongly that they do not elute.

6.16 Cyclosporins

The undecapeptide cyclosporin A is an immunosuppressant agent administered to organ transplant patients, which is slightly better than standard azathioprine and prednisone treatment. Whole-blood monitoring of cyclosporin A (as opposed to untrustworthy plasma analysis) is important in monitoring graft rejection which occurs below the 100 ng mL⁻¹ level. HPLC monitoring has been shown to be more accurate than radioimmunoassay which gave spuriously high results in multiple doses. Bowers and Mathews suggested that a broad unsymmetrical HPLC peak shape associated with the molecule is due to the various tertiary isomers in which the compound exists. Moyer et al. used the minimum retention of a C₁₈ column and elevated temperature to reduce the apparent bandspreading for a more aesthetic chromatogram. Nishikawa et al. found that cyclosporins A, C and D undergo interconversions between two molecular forms, whose chromatographic peak shapes are affected by both temperature and flow rate. Other researchers have used more retentive phases to discern structural cyclosporins and cyclosporin metabolites, differences, particularly with LC/MS analyses. Nazir et al. used a highly selective PGC to separate two cyclosporins that differ in structure by just one methylene group.

6.17 Drugs of Abuse

Reviews of methods of analysis of illicit drugs (also see sections 6.9, 6.20, 6.27 and 6.32) include drug screening in law enforcement, forensic and biomedical sciences, Olympic and Pan American Games sports and the workplace. GC/MS methods are the most prevalent in the literature and are required in the Mandatory Guidelines for Federal Workplace Drug Testing Programs. A dated, yet thorough review of GC/MS methods (which include the GC phases employed) covering publications from 1981 to 1991 was documented by Maurer. Published HPLC methods are also numerous and include review articles by Shihabi and McCormick and Turcant and Kohn.

6.18 Enkephalins/Endorphins

Enkephalins are either of two pentapeptides having the formula, H₂N-Tyr-Gly-Gly-Phe-X, where X is leucine or methionine. Endorphins are any of three peptides: the 30 amino acid C-terminal of β-lipotropin (β-endorphin) [19666-76-3], the 16 residues of the N-terminal of β-endorphin (α-endorphin)[59004-96-5], or the 17 residues of the N-terminal of β-endorphin (γ-endorphin) [61512-77-4]. Both enkephalins and endorphins bind to opioid receptors and are neurotransmitters that play a role in pain perception, among other biochemical functions.

HPLC is clearly the method of choice for determination of these peptides. In particular, several LC/MS methods have been developed that provide powerful analytical data. Common C₁₈ columns are often used in...
these analyses. Several reversed phases were compared by Hearn and Aguilar\textsuperscript{319b} for retention and band broadening of the peptides. Likewise, Purcell et al.,\textsuperscript{320} compared a C\textsubscript{4} and C\textsubscript{18} phase for retention and bandwidth and studied conformational changes of the solutes during chromatographic migration. Conformational changes of \(\beta\)-endorphin on a C\textsubscript{18} phase are believed to occur depending on mobile-phase organic content, flow rate and temperature.\textsuperscript{321,322}

6.19 Glycosides

Glycosides (also see section 6.20) are compounds that contain a carbohydrate molecule, particularly from natural products in plants. Cardiac glycosides occur in certain plants (digitalis, strophanthus, urchina and others) and are biologically active as cardiac muscle contractants. In general, glycosides can be separated on conventional C\textsubscript{18} HPLC phases.\textsuperscript{323,324} GC separations require modification, such as trimethylsilyl derivatization, prior to analysis.\textsuperscript{324–326}

6.20 Hormones

Mueller et al.\textsuperscript{327} reviewed methods for analyzing performance-enhancing glycoprotein hormones by GC/MS. Some early LC/MS methods for analyzing hormones (also see sections 6.17 and 6.32) were summarized by Vouros and Karger.\textsuperscript{328} Other reviews of both LC/MS and GC/MS were published by Shackleton\textsuperscript{329} and Bowers\textsuperscript{330} for steroids, and anabolic steroids and peptide hormones, respectively.

6.21 Mycotoxins

Separations of mycotoxins such as coumarins are probably most often performed by HPLC.\textsuperscript{331} However, Betina\textsuperscript{332} listed many mycotoxin methods (462 references) employing both HPLC and GC. Aflatoxins, ochratoxin A [303-47-9], trichotheccenes, zearalenone [17924-92-4] and patulin [149-29-1] were among the mycotoxin analyses reviewed by Scott.\textsuperscript{333}

6.22 Nitrosamines

Although they are sometimes used as antitumor agent pharmacophores, some nitrosamines are alkylating agents that invoke carcinogenic activity. The deleterious effects of using tobacco goods may partially be due to the presence of nitrosamines in these products.\textsuperscript{334,335} The general public became alarmed when analytical chemists began to find potentially dangerous nitrosamines in many unexpected places such as baby bottle rubber nipples and pacifiers,\textsuperscript{336,337} fried bacon\textsuperscript{338} and protective gloves.\textsuperscript{339} Nitrosamine carcinogenicity may occur by methylation of DNA residues, which can be analyzed by HPLC following hydrolysis. Kawasaki et al.\textsuperscript{340} used this technique to measure cytosine derivatives on a SCX HPLC phase.

6.23 Nucleosides/Nucleotides/Bases

Under the hydrophobic mechanism of HPLC reversed-phase column retention, the elution order (and also the order of polarity) of the titled constituents of nucleic acids is: nucleotides > nucleosides > bases. Bases and nucleosides\textsuperscript{341,342} are generally sufficiently retained and relatively easily separated on C\textsubscript{18} phases. Some C\textsubscript{18} phases may also give adequate retention for simple mixtures of nucleotides. The more lipophilic nucleotides may require special polar interactions for retention, such as those available on IBID reversed phases, or standard normal phases (see section 2.5). Alternatively, the chromatographer might take advantage of the negative charge of the phosphate moiety of the nucleotide molecule in choosing an anion-exchange packing to attain sufficient retention.\textsuperscript{343} Reviews have recently been published on HPLC separations directly related to these compounds.\textsuperscript{344–349}

Nucleotide and nucleoside samples analyzed by GC/MS are often first hydrolyzed to smaller units. Purine nucleosides are easily acid hydrolyzed to the corresponding free base and pentose.\textsuperscript{350} However, pyrimidine nucleosides are more resistant to acid hydrolysis. Nucleosidases may be considered for pretreatment, since they hydrolyze both types of nucleoside. The base is then derivatized to a more volatile form, usually with a silane reagent. Columns typically contain DB-5 or SPB-5 phases. The final MS analysis step may provide useful information as biological markers for cancer, AIDS (acquired immunodeficiency syndrome), and other clinical applications.\textsuperscript{352–354}

6.24 Parabens

Parabens are most often analyzed by reversed-phase HPLC using a C\textsubscript{18} or C\textsubscript{8} phase. These phenolic esters have two major uses in pharmaceuticals. They are frequently used as internal standards for drug analysis\textsuperscript{355–358} and they are present in a variety of formulations as preservatives/excipients. Pharmaceutical preservatives may include methyl\textsuperscript{359,360} ethyl,\textsuperscript{359,361} propyl\textsuperscript{359,360} isopropyl\textsuperscript{360} n-buty\textsuperscript{359,360} and/or isobuty\textsuperscript{360} parabens. It is noteworthy that paraben “preservatives” might actually participate in certain pharmaceutical degradation pathways, such as interactions with sorbitol [50-70-4] and/or glycerol [56-81-5].\textsuperscript{361}

6.25 Peptides

A wide variety of peptide types (also see sections 6.4 and 6.18) and polarities exist and so, too, there is a diversity
of phases that separate them. Review articles summarize choices of reversed-phase, SEC, ion-exchange, hydrophobic interaction, and other phases for peptide separations. Reversed-phase packings, specifically, are covered by Kirkland et al. Evidence provided by Thunecke et al. suggests that a C18 phase catalyzes isomerization of cis-trans peptidyl proline dipeptides. Because of this and other limitations of silica-based packings, nonsilica peptide columns have also been investigated. Certain polymer phases are stable throughout the pH range showing increased selectivity for peptides compared to conventional silica-based reversed-phase packings, but suffer in that they are less pressure stable and may shrink and swell in particular solvents.

Polymer phases that contain polar groups are more favorable for peptide and proteins. Alumina (a Lewis acid) modified with C18 chemistry forms phases that are too active and are not suitable for peptide separations.

Chiral separations on simple peptides have been accomplished on molecular imprint, affinity and brush-type columns. CD chiral phases of various sizes (α-, β- or γ-CD) may be chosen depending on the size of the peptide, as exemplified by Florance and Konteatis. The primary amine residue of peptides can also be taken advantage of by performing chiral separations on crown ether columns.

Peptide and protein separations prevalently use trifluoroacetic acid in the mobile phase. Acid exposure to some reversed-phase columns may catalyze hydrolysis of the bonded phase. Therefore, acid-stable columns are particularly important for these classes of compound (see section 2.4). Another packing consideration is the pore size. The packing material should be chosen so that the solute peptide length is smaller than the pore size of the particle. For medium to larger peptides, a 300-Å pore size is optimum. Smaller peptides may be used on the more universal 100- or 120-Å pore size packings. Packings of 200-Å pore size are also commercially available. Selection of too large a pore size packing is not necessarily desirable, since larger pore particles contain less surface area and, hence, display less retention. When performing calculations for optimum pore size, it is important not to overlook that the manufacturer’s listing of the pore size is for the bare particle before bonding. A catalogued 120-Å C18 phase actually has an effective pore size somewhat less than that, since the bonded C18 molecule occupies space within the pore.

GC/MS peptide analysis involves hydrolyzing the peptide and then derivatizing the individual amino acids or fragments before injection. Columns include DB-1, BP-5, and PS255. One particularly interesting publication by Cano used this general procedure to characterize 2- to 135-million-year-old bacteria. Study of ancient bacteria might lead to production of novel antibiotic, fungicidal, etc., proteins and peptides.

6.26 Pharmaceutical Processing Solvent Residues

Granules, tablets, film coatings and plastic sealants used for pharmaceutical drugs may contain harmful solvent residues. Analytical monitoring of these solvents is accomplished by headspace GC analysis using phases such as methyl silicone-coated columns. Foust and Bergren developed a separation method for 27 solvents which required just 20 min.

6.27 Phenylalkylamines

Phenylalkylamines (also see section 6.17) are important structures in pharmaceutical drug design and analysis. The solute’s basic residue is subject to active silanol interaction resulting in peak tailing. Active C18 phases typically show tailing, even when low-pH mobile phases are used in the attempt to protonate the active silanols. Similarly, Murayama et al. found that a titania C18 phase is very active for phenylalkylamines. Base deactivated reversed-phase HPLC packings are the best choice for these solutes (see section 5.2).

Mauret performed GC/MS analysis on some derivatized amphetamine designer drugs using a methylsilicone-coated column. For chiral separations of primary amine phenylalkylamines, chiral crown ether columns (see section 5.7) may be utilized.

6.28 Porphyrins

Naturally occurring cytochromes contain iron–porphyrin groups involved in electron-transfer systems or hydroxylation reactions. Hematoporphyrin compounds, which are tumor localizers, have been separated by HPLC on C18 or C8 phases with UV detection at 360–400 nm. A bare silica normal-phase column has also been used by Dellinger and Brault. Conventional C18 phases were utilized in separating other porphyrin compounds including porphyrin c and N,N'-diacetylporphyrin c. Tin protoporphyrin 14325-05-4 and other metalloporphyrins were separated on a DVB phase.

6.29 Procaainamides

Antiarrhythmic procaainamides are separated on a variety of reversed-phase columns including C18, heptyl, cyano and phenyl packings. Gisch et al. found a t-butyl phase gave better peak shapes than an n-butyl phase, presumably owing to improved shielding of undesirable silanol interactions by the former bulky substituent. Although procaainamides...
are not as problematic regarding tailing as are tricyclic antidepressants, they still are sensitive enough to be useful as a first test for packing silanol activity. Several column manufacturers have adopted these solutes in quality control analysis of their bonded phases. Propanilamides are also used as internal standards in many HPLC analyses including ranitidine [66357-35-5] and propranolol [318-98-9].

6.30 Profens
The profens (also see section 6.5) are readily separated on common C18 phases. Profens may display good peak shape on active type A packings since they are acidic in nature, but type B phases also perform well (see section 5.1). Enantiomer separations of profens are acidic in nature, but type B phases also perform good peak shape on active type A packings since they are acidic in nature, but type B phases also perform well (see section 5.1). Enantiomer separations of profens is well studied, including isolations on brush-type cellulose [408-809] 1-leucinamide, [410] OVM, [411] AGP, [412] ergot alkaloid, [413] avidin [414] and CD [415] phases.

6.31 Proteins
The same generalities associated with the chromatography of large peptides (see section 6.25) also hold true for proteins. Reviews have been published on the choice of phase and mode of separation for protein separations, including reversed-phase, hydrophobic interaction, ion-exchange, gel permeation, bioaffinity, and other types. More polar stationary phases are desirable in cases where retention of protein integrity and function is needed. Reversed phases denature proteins, thereby destroying their biological activity. A hydroxymethyl methacrylate phase by Coupek and Vins exemplifies a "protein-friendly" phase.

Pore sizes become an important factor in selecting phases for larger protein analytes. The pore should be adequately large enough to accommodate the solute. Packings of 300 Å are of sufficient size for most applications. For proteins approaching a molecular weight of about 500 000 Da or more, a 500-Å phase may be the best choice.

Proteins are somewhat unique in that there is no typical adsorption–desorption mechanism normally occurring in reversed-phase separations. Instead, the proteins apparently stick to the packing material until a "magnetic" ratio of % aqueous: % organic mobile phase composition is reached under gradient conditions, which releases the proteins from the phase. Another particular trait of some peptides and proteins is that they may adhere to SS column and frit surfaces. For this reason, some chromatographers prefer to run protein HPLC separations using all PEEK® connective tubing and column hardware. More extensive studies in this area are needed to quantitate protein interaction with various material types.

6.32 Steroids
Both reversed-phase and normal-phase columns may be used for analyzing steroids (also see sections 6.4, 6.5, 6.17 and 6.20). The cyano phase works by either mechanism, depending on the mobile phase employed. It gives excellent separations, but is often overshadowed by the use of the more familiar C18 phase. Reversed-phase methods exist for anabolic steroids, corticosteroids, bile-acid steroids, cholesterol steroids, phytoecdysteroids, brassinosteroids, and oysterols. An interesting property of steroids in chromatographic separations is that they tend to show improved separations at lower temperatures, akin to chiral separations.

Low-volatility steroids can be analyzed by GC/MS, including the edysteroids. Steroid profiling is another good application for GC/MS analysis as reviewed by Honour.

6.33 Sulfur Drugs
Reversed-phase C18 HPLC packings are most often used for analysis of sulfur compounds related to pharmaceutical applications. The antibacterial sulfa drug, sulfadoxine [2447-57-6], was measured in plasma by Astier et al. and Kohl et al. determined disulfiram [97-77-8] and sulfamethoxazole [723-46-6] in urine. Sulfatrim [723-46-6] dissolution and elemental sulfur [7704-34-9] in pharmaceutical preparations and reflux tests were also conducted on C18 phases. Dangi et al. measured sulfur mustard [505-60-2] in blood samples on a C18 phase with UV detection at 200 nm.

Consumer concern over the practice of routinely adding antibiotics to animal feeds has led to the development of methods to analyze these additives in food products. Hougum et al. determined sulfamethazine [57-68-1] in animal feeds with a C18 phase. The additives may become incorporated in the meat products, which also is desirable to analyze for health reasons. Thus, Milner et al. resolved sulfadimethoxine [122-11-2] in fish fillets. Sulphadiazine [68-55-9], sulphadimidine [57-68-1], sulphamethoxine [122-11-2], sulfadoxine [2447-57-6], sulfamerazine [127-79-7], sulfamethoxazole, sulfamonomethoxine [1220-83-3], sulfaquinoxaline [59-40-5], sulfathiazole [72-14-0] and sulfasomidine [515-64-0] were measured in beef, chicken and pork meats. Patthy and Elementary sulfur [436-24-2] were analyzed in chicken meat and liver.

Chiral separations for N-aryl thiazolinones and their derivatives were run on a brush-type phase. A dimethylsilicone phase was used for GC/MS analysis of anticarcinogen components in garlic extract.
6.34 Taxol and Related Compounds

Taxol [33069-62-4] and related compounds are under intense study for their antitumor and antileukemia activities. These natural products are extracted from yew trees for experimentation and drug development. Chromatographic analyses have been developed for isolating the products from the yew bark, leaves and/or stems, using C\textsubscript{18} or C\textsubscript{8} (450–453) cyano (454–456) phenyl (456–458) porous graphitic carbon (459–461) PFP (98, 462) and special phases designed especially for taxol separations. (463, 464) Limited supplies of yew trees prompted research into growing cell cultures to be harvested for their taxol production. Analytical and preparative methods have been developed for this purpose. (465–468) Methods have also been developed for monitoring taxol levels in experimental mouse plasma models (469–471) and human biological fluids and tissues. (472–482)

6.35 Terpenes

In general, GC/MS is currently the leading technique in analyzing terpenes (also see section 6.4). For example, the naturally occurring α-terpineol [98-55-5] is an antiseptic drug found in petitgrain oil, long leaf pine oil, cajeput oil, gentian roots and other sources. It has been analyzed on PEG phases (483, 484) and a cholesteryl acetate phase. (485) Separation of the enantiomers has been investigated on substituted CD phases (486, 487).

6.36 Tetracyclines

Comparisons were run between several C\textsubscript{18} and C\textsubscript{8} phases for the assay of tetracycline hydrochloride. Under various conditions the C\textsubscript{8} phases performed as well (488) or better (489) than the C\textsubscript{18} phases. Polymer phases appear to offer advantages over even base deactivated C\textsubscript{18} phases in peak shape, separations and recoveries of oxytetracycline [6153-64-6], tetracycline [60-54-8] and chlortetracycline [64-72-2]. (490) Although tetracycline is not a particularly large molecule, 1000-Å pore polymer particles seem to be optimum for this solute. (491, 492)

In addition to urine (493) and serum (494) analyses, tetracycline is measured in meat, milk and cheese owing to health concerns. (495) An HPLC method was also developed for this drug in discolored teeth, which was found to be caused by incorporation of minocycline [10118-90-8] into the dentine and enamel. (496)

6.37 Tricyclic Antidepressants

Drugs within the class of tricyclic antidepressants represent some of the most challenging compounds to obtain good symmetry in HPLC separations. They are relatively strong bases that can have undesirable potent interactions with active silanols. Type B reversed-phase silica packings are highly recommended for these compounds. Most literature separations using C\textsubscript{18} phases, whether they are deactivated or not, use ion-pairing (497, 498) or ion-suppression (499, 500) additives, and/or acidic mobile phases. (501, 502) Acidic mobile phases with cyano phases often provide better peak shape than hydrocarbon phases. This is reflected by the appearance in the literature of several publications using cyano columns. (503–505) Mixed phases have also been used to improve peak shapes of tricyclic antidepressants. (509) An approach to choosing the best stationary phase is described by Kirkland and Henderson. (510) Some direct chiral separations of tricyclic compounds were performed on an AGP (see section 5.7) phase. (511)

Separations by GC are not as prevalent as HPLC methods. Columns used include DB-1, (512) OV-1 and OV-25 (513) and SPB-1. (514)

7 ASSOCIATION OF OFFICIAL ANALYTICAL CHEMISTS AND UNITED STATES PHARMACOPEIA METHODS

Appointed volunteers from all over the world perform collaborative validation work in providing the AOAC (Association of Official Analytical Chemists) Official Methods. The studies are designed to establish accuracy, precision, sensitivity, range, specificity, ruggedness, limit of measurement, practicality and other parameters of methods under typical laboratory conditions. The methods are used in government regulations, various commercial product analyses, legal proceedings, and in requirements for some national and international trades. Collaborative study reports for first action methods are published in the Journal of AOAC International, while both first and final action methods are published in the compendium, Official Methods of Analysis.

The United States Pharmacopeia (USP) provide similar services in developing methods. Regarding bonded phases, a USP method may specify a particular packing type. A list of some USP column classifications is shown in Table 4.

Other assistance available to the chromatographer includes a large selection of applications available from the various commercial column manufacturers. Although most applications are run with standards rather than “real-life” samples, the general separations and retention characteristics furnish a good starting point for column selection and chromatographic conditions. Many chromatography column companies offer technical support to assist in the decision making, albeit somewhat biased, naturally, towards the manufacturer’s products. The largest convention, by far, for HPLC and GC column manufacturers is the yearly Pittsburgh Conference normally

Mass spectrometry (MS) applied to the biological sciences in the pharmaceutical industry covers a broad range of application topics, such as quantitative analysis of drugs in physiological fluids, qualitative analysis of noncovalent complexes, structural analysis to determine chirality and protein sequence analysis. Regardless of the application, electrospray ionization (ESI) is the primary ionization method for transfer of nonvolatile biologics like proteins and peptides into the gas phase for analysis. It is most often used as an interface between high-performance liquid chromatography (HPLC) separation methods and MS. The ESI process converts analytes in solution to ions in the gas phase via electrostatic nebulization at atmospheric pressure. It is characteristic of ESI to produce multiply charged analytes in a concentration-dependent manner that is sensitive to changes in solvent, pH and ionic strength. A high voltage is applied to a liquid containing analytes as they traverse a capillary, and when the liquid droplets exit this capillary at atmospheric pressure they are directed into the source region of a mass spectrometer where desolvation is completed. Ions are then focused by an electronic gradient across a series of lenses and separated by mass/charge (m/z) using various mass spectrometer designs. Currently, the two most popular mass separation devices are quadrupoles (either single or triple quadrupole (TQ)) and ion traps (ITs). Both types of mass spectrometers are used with ESI to achieve sensitivities as low as attomoles ($10^{-18}$ mol) of analyte injected onto a microcapillary HPLC column. The type of analyte, as long as it is capable of accepting a charge (addition of $H^+$ or loss of charge in negative ion mode) is relatively transparent to ESI and so a diverse range of analyte classes with disparate molecular weights can be ionized, from peptides ($500–5000$ amu) to proteins ($10,000–100,000$ amu). Depending on the construction of the source, ESI can be carried out with reversed-phase HPLC at flow rates from $200$ nL min$^{-1}$ to $2$ mL min$^{-1}$ and also with capillary electrophoresis. The ease of use of ESI compared to prior techniques like fast atom bombardment...
has made it very popular with biologists, chromatographers and chemists who might not otherwise have been interested in MS. In fact, for many scientists ESI has made MS almost as “user-friendly” and thus accessible as an ultraviolet (UV)–visible detector for HPLC.

1 INTRODUCTION

The modern pharmaceutical laboratory utilizes MS for many purposes, including basic biological research, quantitative analysis, qualitative analysis and routine monitoring for quality control of products. Before the mid-1980s and fast atom bombardment ionization, MS was mainly used for the quantitation of small volatile organic molecules and structural analysis via chemical and electron impact ionization. The incorporation of MS into all aspects of pharmaceutical research was made possible by two developments in the late 1980s, specifically the development of two ionization methods, which revolutionized the way in which biological analytical sciences were conducted. These two ionization methods or techniques – ESI and matrix-assisted laser desorption ionization (MALDI) – gained immediate popularity because of their ability to ionize, without significant fragmentation or prior derivatization of analytes, nonvolatile biological molecules such as proteins and peptides. For many laboratories ESI quickly replaced fast atom bombardment as the interface between HPLC and MS, owing to the ease with which it could be adapted to scanning instruments such as quadrupoles. Furthermore, the ESI process allowed simple quadrupole instruments with a limited m/z range to detect analytes outside the m/z range of the instrument, because of the addition of multiple charges to analytes during the ESI process.

Qualitative MS is often used to help biologists gain insight into biological processes or systems. Understanding noncovalent, intermolecular interactions between two macromolecules, between a small molecule and a macromolecule or simply mapping disulfide bonds within a protein can be performed much faster with MS than traditional methods. Studies similar to these can provide details about how a receptor molecule may bind a ligand, providing important information prior to crystal growth for crystallographic studies. For instance, cross-linking a ligand to a receptor, followed by enzymatic digestion and MS analysis, provides information about sites juxtaposed under native conditions that is valuable for the interpretation of crystallographic data. If the receptor–ligand complex cannot be crystallized, then the MS data may be the only route to understanding the interaction.

Quantitative studies have been, and continue to be, an important application of MS. With the advent of ESI, the variety of molecules accessible for analysis became much wider than when electron impact, chemical ionization and fast atom bombardment were the only good choices for ionization. Generally, MS has been used to quantitate small organic molecules (<500 Da) in plasma and urine. However, even large molecules such as proteins can, with an appropriate standard, be quantitated using ESI or MALDI without enzymatic digestion to peptides. Quantitation of peptides in plasma and urine is remarkably similar to the analysis of small molecules from these matrices. Peptides, however, generally suffer from poor pharmacokinetics after oral administration, which is generally due to the short half-life observed for many peptides. This is often controlled through modification of the structure to prevent rapid digestion by proteolytic enzymes present in the gut and circulatory system.

MS now is also used for routine sequencing of proteins for the drug discovery process. With the advent of DNA and protein databases, MS has replaced Edman chemistry as the method of choice for sequence analysis for all but complete unknowns. The MS sequence methods rely on a database search and a mass spectrometer to provide information about masses. The database search may be used to identify a novel protein or, if the protein is known, to determine its sequence. Edman chemistry will, however, be of importance for sequence analysis of organisms for which no genome sequence is available and for post-translational modification such as phosphorylation of certain peptide sequences that are intractable to MS methods.

In addition to the use of MS in basic research, the application of this technology for quality control is important. Methods that allow for rapid assessment of drug substance batch-to-batch quality are routinely devised, as are methods for the analysis of peptide or protein purity. After a review of the basic MS instrumentation currently in use and some general aspects of working in an analytical laboratory, examples will be provided for MS applications in the qualitative analysis of peptides in urine, chiral analysis of peptides, comparative MS/MS analysis and thermal denaturation of DNA complexes. All of these topics are of widespread interest and constitute ongoing areas of analytical development in the pharmaceutical science. For many of these applications, the type of analyte used is more or less transparent to the analytical process and thus is useful for small molecules as well as peptides and proteins.

2 BIOLOGICAL MASS SPECTROMETRY

2.1 Mass Spectrometers

At the simplest level, MS consists of three processes: ionization (e.g. MALDI or ESI); mass (m/z) separation.
(e.g. time-of-flight (TOF), quadrupole, IT); and ion detection. Ion detection, being mostly MS instrument independent, will not be covered here. Analytes in solution or as crystals on a surface are converted to ions by the ionization process where protons/electrons are added or subtracted to impart some detectable m/z value. Ions are then separated from each other in vacuo based on a process that is dependent on the type of mass spectrometer being used. For protein and peptide applications, the four most common types of mass spectrometers utilized are MALDI coupled to a TOF mass spectrometer and ESI coupled to a TOF, a single quadrupole (SQ) or an IT mass spectrometer. The applications presented in this chapter will focus on ESI and so MALDI coupled with a TOF mass spectrometer will not be reviewed directly.

### 2.2 Electrospray Ionization

In ESI, the analyte solution passes through a needle to which a high potential (\(\sim 1000–5000 \text{ V}\)) is applied at atmospheric pressure.\(^{(11,12)}\) This results in electrostatic nebulization of the liquid, producing charged liquid droplets that are directed to the mass spectrometer inlet, which is at some lower potential than the ESI voltage. As the charged droplets traverse the source region they are desolvated by various processes, depending on the instrument design. The process by which analytes in solution are converted to ions in the gas phase continues to be a topic of debate among research laboratories and will not be discussed further. After desolvation, solvent-free ions are focused through a series of lenses into the mass analyzer. It is characteristic of the ESI process to produce peptide ions bearing multiple charges. The number of observed charge states is a function of the number of ionizable groups contained in the analyte. The observed distribution of charge states can be affected by changes in pH, solvent and tuning conditions.\(^{(13,14)}\) For instance, tryptic peptides analyzed by positive ion mode electrospray ionization/mass spectrometry (ESI/MS) at a pH of 3.5 will normally carry at least two charges.\(^{(15)}\)

This is because the hydrolysis of a peptide bond by trypsin leaves a lysine or arginine amino acid at the carboxyl-terminus of the peptide. In general, peptides and proteins will bear a number of charges in positive ion mode roughly equivalent to the number of basic residues, such as the amino acids lysine, arginine, histidine and proline, present in the sequence. If the protein or peptide is of unknown molecular weight, adjacent charge states can be used to determine the molecular weight. Most instruments come with software to do this deconvolution but it is based on simple algebra. To determine molecular weight from the mass spectrum of an unknown analyte we can use the mass spectrum in Figure 1 as an example. Choose two adjacent charge states suspected of being related and fill in the following equation: \(m/z_2/(m/z_2 - m_1) = (649)/(649 - 433) = 3\). If this algebra produces an integer, as in this case, then the integer represents the number of charges (e.g. in positive ion mode protons or sodium ions) on \(m_1\); i.e. 433 is an \([M + 3H]^{3+}\) ion. If \((m/z_2)/(m/z_2 - m_1)\) produces a noninteger, then the adjacent \(m/z\) values are not related (i.e. they arise from different analytes or the same analyte but have different charge-bearing adducts). Molecular weight is then obtained from the following equation: \((m_1)(m/z_2)/(m/z_2 - m_1) - (m_2)/(m/z_2 - m_1) = (433)(3) - (3) = 1296\). Note that for the negative ion mode of peptides, protons are removed from the peptide.

### 2.3 Electrospray Ionization/Quadrupole Instrumentation

Quadrupoles consist of four parallel rods with opposite pairs of rods connected electrically carrying DC and AC voltages of opposite polarity. Voltage is varied across the rods such that at a given moment in time only ions of a certain \(m/z\) ratio oscillate in a synchronous and linear path through the filter. All other ions follow a nonlinear trajectory out of the quadrupole and are lost. To produce a mass spectrum, the quadrupole is ‘‘scanned’’ across a defined \(m/z\) range. A typical scan with a quadrupole instrument takes several seconds, because the AC and DC voltages are varied for a scan and then reset to start again. In contrast TOF and IT mass analyzers acquire an entire mass spectrum in milliseconds. A TOF mass analyzer has a theoretically unlimited \(m/z\) range and so is popular for analyzing proteins, whereas quadrupoles and ITs are typically limited in \(m/z\) range, thus relying on the multiple charged observed with ESI sources to analyze high-molecular-weight compounds.

A TOF mass spectrometer consists of three sets of quadrupoles that can either transmit all ions (i.e. radiofrequency (RF)-only mode of operation) or function as a mass filter allowing ions of a specific \(m/z\) to pass.\(^{(16)}\) Generally the first (Q1) and third (Q3) quadrupoles function as mass filters whereas the second quadrupole (Q2) always operates in RF-only mode. When filled with argon (\(\sim 3–5 \text{ mTorr}\)) and with an accelerating voltage applied, Q2 serves as a collision cell, passing all fragment ions from a precursor ion selected by Q1. There are five basic modes of operation for a TOF:

1. In **MS mode**, Q1 or Q3 is scanned to produce a ‘‘main beam’’ or standard mass spectrum whereas the non-scanned quadrupole functions in RF-only mode. This scanning mode would provide data that are exactly analogous to the data that one would observe using an SQ instrument.
2. **In MS/MS mode.** Q1 transmits ions of a selected m/z. These ions are accelerated into Q2, which is filled with argon gas to generate fragment ions. These fragment ions are then transmitted by Q3, which is scanned to produce a mass spectrum consisting of fragment ions originating from the Q1-selected m/z ion.

3. **In neutral loss mode.** Q1 and Q3 are scanned simultaneously but with Q3 at an m/z offset, corresponding to a neutral loss of interest (e.g. doubly-charged phosphorylated peptides can be detected by scanning for a neutral loss of 49 m/z (loss of H₂PO₄⁻) that undergoes a facile β-elimination). The resultant mass spectrum consists only of ions that lose the specified neutral m/z fragment.¹⁷

4. To generate a **precursor ion scan.** Q1 is scanned while Q3 transmits ions of only one select m/z value. Thus, all ions transmitted through Q1 are sequentially fragmented in Q2 and any that produce a fragment ion equal to the m/z value set for Q3 produce the so-called precursor ion mass spectrum.¹⁸

5. **In-source fragmentation** provides an opportunity for triple MS on a TOF instrument or MS/MS on an SQ instrument, or in negative ion mode as a diagnostic ion scan for loss of phosphate from a peptide.¹⁹ Fragmentation occurs in a high-pressure region of the differentially pumped ESI source, as a result of collisions with atmospheric gases. It is an indiscriminate process where charge states with n > 1 are preferentially fragmented by imparting a greater amount of kinetic energy than is necessary to simply focus the ions into Q1. All of the above scan types, 1–4, can be carried out on ions generated by in-source collision-induced dissociation (CID).

The two most commonly used MS modes for quantitation are variations on the MS mode and MS/MS mode described above: specifically, selected ion monitoring (SIM), which is sometimes referred to as multiple ion monitoring; and selected reaction monitoring (SRM), which is sometimes referred to as multiple reaction monitoring. These methods of quadrupole operation are important for quantitative analysis. An example of SIM quantitation is presented in section 5. Generally in quantitative studies, a stable isotope label of the drug substance or an analog similar in chemical properties to the drug substance is added as an internal standard (see section 5, where this is discussed in depth). The internal standard is added at a constant amount to the biological sample prior to any sample preparation. Once the sample has been prepared, it can be injected onto the mass spectrometer. In SIM mode, the mass spectrometer scans a small m/z window (typically <0.4 amu) at the m/z of both analyte and internal

---

**Figure 1** Results from Liquid chromatography/mass spectrometry (LC/MS) system suitability standard test. (a) Total ion chromatogram (TIC) for 500 fmol of angiotensin and single ion chromatogram (SIC) for the 3+ ion. (b) Abscissa magnified around the SIC of the 3+ ion and the same mass spectrum with the ordinate magnified 1000×. Data acquired on an SQ scanning 300–1500 amu in 1.5 s.
standard. This is repeated continuously over the entire chromatographic run. The areas under the curve for each standard concentration are then plotted, so that a linear regression can be used to calculate the quantity of analyte in each unknown sample. It is important to prepare the standard curve in the same matrix that will be used in the study and that the analysis of standards and samples be reproducible. The second type of method commonly used for quantitation is SRM. This technique has significant advantages over SIM in both selectivity and specificity, resulting in a potential speed advantage. In this mode, the TQ remains in MS/MS mode and continuously switches between two different MS/MS reactions: one for the analyte and one for the internal standard. Specific fragment ions, instead of precursor ions, as with SIM, are used for quantitation. Many laboratories are utilizing SRM quantitation with TQs, to achieve the lowest possible detection limits for potent drug substances. The selectivity and specificity of SRM reduces the amount of chromatography required, thus time-consuming (i.e. costly) chromatography can be avoided. Chromatography is still utilized, but it is done rapidly, where an entire run may only last a few minutes. Generally the analyte is desalted, retained on the column for a short period of time and eluted. With an isocratic method, limited column equilibration is required. With a rapid gradient method, as short as possible column re-equilibration is performed. Samples in very complex matrices can be analyzed with little clean-up prior to analysis owing to the specificity of the MS/MS reaction. The sample clean-up is still required with SRM quantitative studies, owing to the ion suppression effects of salts, proteins, and other endogenous compounds. It is also important to demonstrate, through the analysis of blanks, that no endogenous compounds interfere with the analyte-to-fragment ion transition selected for quantitation because it is the unique combination of analyte mass and fragment ion mass that identifies one analyte from another.

2.4 Electrospray Ionization/Ion Trap Instrumentation

A major difference between a TQ and an IT mass spectrometer is that in an IT instrument the mass analyzer also serves as the collision cell. Quadrupole ITs use RF-only quadrupoles to guide ions from the ESI source into the IT, similar to quadrupole instruments. The mass analyzer is significantly different, however. Two different types of electrodes are used to create the IT: a ring electrode and two end-cap electrodes. Ions enter and leave the trap through holes in the end-cap electrodes and are trapped in a field created by applying an RF voltage to the ring electrode. The magnitude of the voltage determines the frequency and motion of trapped ions. Ions above a certain \( m/z \) remain in the trap and are collisionally cooled to stabilize their trajectories with helium gas. This results in a collapse of the sinusoidal cycling of ions from a larger to a smaller trajectory over a short period of time. A mass spectrum is acquired by ramping the RF voltage linearly while applying a small voltage across the end-cap electrodes, which causes “resonance ejection” of ions of successive \( m/z \). Resonance ejection refers to ions becoming unstable in the trap and thus being ejected axially through the end-cap electrodes, where they are detected by an off-axis conversion dynode with an electron multiplier detector.

Through this ion trapping/ejecting process, tandem MS experiments (MS/MS) and MS\(^n\) experiments are conducted. The process of fragmenting ions in an IT begins by ejecting all ions at larger and smaller \( m/z \) than the ion of interest. Once the IT contains only the \( m/z \) of interest, the selected \( m/z \) value is energized by altering voltages on the electrodes, so that it collides with the dampening gas (helium). Fragment ions are then detected by scanning out all of the ions from the trap, as described above. If sufficient signal persists, further rounds of MS/MS (MS\(^n\)) can be conducted by leaving a fragment ion of interest in the trap for additional fragmentation events. The amount of energy imparted to the trapped ion can be varied with a parameter referred to on some instruments as the relative collision energy. Other parameters that can be varied on an IT include the number of ions allowed to enter the trap in any one event and the number of such events performed in replicate for averaging purposes (i.e. increasing signal-to-noise). Commercial IT mass spectrometers have data-dependent fragmentation capabilities and are therefore ideally suited to liquid chromatography/tandem mass spectrometry (LC/MS/MS).

3 SAMPLE HANDLING CONSIDERATIONS

3.1 Sample Handling for High Sensitivity

This field is better known as microsample handling and is of significant importance to those working with any sample that can be described by the phrase “the world’s supply”. This usually means that the biologist is nervous about handing over six months’ worth of work to someone with no direct appreciation for the precious sample. Or it may mean that the samples are worth thousands of dollars and the study (e.g. clinical trial) cannot be repeated easily. There are some simple rules worth mentioning that can be followed for working with peptides and other small molecules. Generally, almost any transfer or purification step applied to a sample will reduce the quantity by 50%. This is a generalization of course, but the point is to plan carefully the route from
tube to MS so as to avoid potential sample loss. Complete lyophilization to dryness should be avoided because some peptides (and other analytes as well), once dried in a polypropylene tube, will not go back into solution. It is of course impossible to predict a priori which will behave this way. Often new columns will irreversibly adsorb a portion of the sample, thus new HPLC columns should be preconditioned prior to injecting a valuable sample. Finally, the mass spectrometer should be tuned using an analyte that is as near identical to the sample and under the same conditions that the sample will be introduced as possible. Failure to tune the MS under appropriate conditions can easily negate any advantage provided by careful sample handling.

3.2 Chromatographic Considerations

In the field of Proteomics, working with the smallest i.d. capillary HPLC columns possible is a requirement in order to avoid sample loss and to optimize sensitivity. Samples, often present at the limit of detection, are extracted from polyacrylamide gels and any manipulation of sample must be minimized. LC/MS sensitivity is optimized by using 50-µm i.d. capillary liquid chromatography (LC) columns packed using stainless-steel chambers (Mass Evolution, Houston, TX) pressurized to 1000 psi. Samples are loaded directly using the same pressure chamber into the capillary column without any chance for loss present in a normal injector where transfer to a syringe is required. The fused silica capillaries (50 µm i.d.) are slurry packed to 10 cm with C18 silica beads in 70% ethanol. Porous frits are placed at the capillary terminus to hold the packing in place by sintering underivatized silica beads (LichroSorb Si60) in a flame. Peptides are eluted quickly with a fast linear gradient of 0–60% solvent B in 15 min at 150 nL min\(^{-1}\). Standard HPLC pumps operated at 50 µL min\(^{-1}\) can be used for the microcapillary column described above using a precolumn restrictive flow splitter that is 50 µm i.d. and 200 cm in length. This fast gradient method, together with a trace amount of ion pairing reagent, maximizes the chromatographic resolution and produces a sharp elution profile. Typical solvents are aqueous with 0.2% acetic acid and 0.005% heptafluorobutyric acid in one pump and acetonitrile alone in the second pump. Acid is not needed in solvent B for good chromatography and its addition only increases the chemical noise observed in the mass spectrometer. For such small columns, microspray sources are easily and economically constructed from commercially available baseplates and parts (Mass Evolution, Houston, TX), such as a Valco stainless-steel union to which the ESI voltage is applied. Capillary columns terminate inside the Valco union and a fused silica capillary (10 cm × 50 µm × 180 µm) manually tapered to ~5 µm serves as an emitter. No sheath gas or liquid is necessary for such small flow rates. This same device can also be used in negative ion ESI/MS. These techniques have been used to great advantage for sequencing and identifying peptides present in extracts at the very limit of detection by ESI/MS in the fields of apoptosis and immunology. Additional examples of the use of microcapillary columns to solve structural problems in biology can be found at the World Wide Web site: http://staff.washington.edu/goodlett.

3.3 Electrospray Ionization Advantages

An additional advantage can be made of the concentration-dependent nature of ESI, which allows the flow of liquid through an ESI source to be decreased or modulated relative to some normally constant flow rate during a separation without sacrificing sensitivity. The advantage provided by a reduction in flow through the ESI source can be thought of as follows. If at a given moment in time (i.e. one scan) 100 analyte molecules pass through the ESI source and there is current available to convert only ten analytes to ions in the gas phase, then 90 will be wasted. By reducing the flow through the ESI source, the available ESI current can be utilized more efficiently. Consider the following simplified example where flow is reduced and the chromatographic “peak” broadened such that 25 analytes instead of 100 pass through the source during one scan. Now, with the only experimental change being reduced flow through the ESI source, such that there is still enough current available to convert ten analytes per scan to ions, only 15 analyte molecules are wasted per scan. The next three MS scans across this broadened “peak” will detect, in turn, 30 analytes as ions. So, instead of 10% of the sample being analyzed, 40% is analyzed via this reduced elution speed process. This may seem insignificant, but it has proven to be important for both electrophoretic and capillary liquid chromatography/electrospray ionization/mass spectrometry (LC/ESI/MS) applications. Several names have been used to describe this process, including “peak parking” and “voltage drop”, regardless of the name, it is the concentration-dependent nature of ESI that allows more time for analysis across a given chromatographic area without sacrificing sample.

4 GENERAL LABORATORY

4.1 Following Good Laboratory Practice

Good laboratory practice (GLP) regulations are a management-based quality system enforced by the Food and Drug Administration (FDA) for nonclinical studies.
It is intended for nonclinical laboratory studies that support applications for research or marketing permits for products regulated by the FDA. Laboratory analysis done for clinical trial support is also expected to be done under GLP. In general, following GLP is mainly about using a commonsense approach to laboratory management. Scientists are asked to record all work in a logical and reproducible manner such that it can be easily repeated or reconstructed. It involves signing and dating all notebook entries so that a trail is left for decision-making in future experimental design and for auditors. Standard operating procedures should be developed and adhered to for instrumentation used in the various studies. Instrument maintenance logs are kept for each piece of equipment so that trouble-shooting can be carried out logically and orderly. Instruments should be tested routinely to ensure that they are in good working order. When a system that is routinely tested using the same conditions fails, then logical systematic procedures should be in place to correct the problem. Each set of experiments should include, at the very least, a set of system suitability checks (i.e. standards and blanks run under conditions identical to the unknowns) placed at the beginning and end of each data set to ensure that the instrument or system is, and has, functioned properly over the course of the analysis.

For LC/MS systems there are four tests that the system suitability standard can assess:

1. Is the HPLC system functioning properly?
2. Are the solvents clean?
3. Is the mass spectrometer tuned and calibrated properly?
4. Is the HPLC column and associated plumbing in good condition?

All of these questions can be answered by one LC/MS analysis performed prior to analyzing real samples. To answer these questions a system suitability standard is designated for the laboratory LC/MS work. It should be an analyte in the same class as that being analyzed or a well-characterized sample. For example, a system suitability test for microcapillary high-performance liquid chromatography/mass spectrometry (HPLC/MS) using a 50-µm i.d. × 10-cm C18 column could be the analysis of 500 fmol of angiotensin. The peptide is injected onto the capillary column and then eluted under standard linear gradient conditions (Figure 1a). The results obtained are analyzed in light of the above questions. If the HPLC system has functioned properly to deliver solvents as programmed, then the elution time for the peptide will be reproducible. If elution time is outside of the expected range, then either the HPLC system is not functioning as programmed or perhaps the column is beginning to fail. The peak shape should be symmetrical and elute over a short time period of 10–15 s (Figure 1b). If the peak is too broad or not symmetrical, then there may be a problem with the chromatography or perhaps additional dead volume has been introduced somewhere in the HPLC system. If the HPLC/MS system is working properly, then the signal-to-noise ratio of the analyte should be above a preset value. If the signal-to-noise ratio of the analyte is below an acceptable value, then perhaps the solvents should be changed or the mass spectrometer cleaned. For a 500-fmol angiotensin injection on the above-mentioned capillary column dimensions, a signal-to-noise ratio of at least 1000:1 should be attained at the apex of the chromatographic peak (Figure 1c). Finally, the calculated and observed molecular weight for the analyte (angiotensin) should match closely. Of course many of the potential symptoms and problems in an HPLC/MS system are related and some skill is needed to ascertain the exact cause of decreased system performance. However, a simple, well-designed, well-characterized, robust system suitability test carried out prior to the analysis of samples would provide confidence in the observed results and should enable the novice operator to begin trouble-shooting a complex scientific instrument if something were to go wrong.

4.2 Automation

Almost every step in the sample analysis process can be and has been automated. Some automated processes are more efficient than others, but all automation is driven by the high costs of drug discovery and production. This cost includes employee costs and the years of research prior to discovery that are followed by methodical FDA testing requirements once a new drug candidate has been identified. The desire for higher throughput in pharmaceutical companies can be observed easily from the combinatorial chemistry initiatives being employed at almost all companies. The need for larger compound libraries, in the hopes of finding better lead candidates, has relied heavily on the automation of numerous synthetic procedures. MS has been utilized heavily in the combinatorial chemistry field, performing rapid molecular weight measurements, high-throughput purification, and decoding libraries from hundreds of combinatorial chemistry samples per day. Almost all of the MS instruments utilized in the combinatorial field are part of an automated system, where multiple probe injectors, high-capacity autosamplers, fraction collectors, analog detectors, and liquid delivery systems are used together. With the increased size in focused libraries, additional needs have been placed on the discovery research groups responsible for lead identification, development, and selection. These groups have begun to utilize robotic liquid handlers, 96-well solid-phase extraction (SPE), fast generic gradient methods, and as many mass spectrometers as necessary to analyze
samples as rapidly as possible from a variety of in vitro and in vivo screens. From sample work-up to data analysis, devices have been built that free chemists for nonroutine tasks that require problem-solving skills. This drive to increase throughput and efficiency can be beneficial for scientists operating in this environment. The increased use of automation may enable employees to focus on the creative processes of managing projects, understanding processes, and interacting with other scientists to understand better the important scientific problems facing society today.

In the field of protein discovery science, data-dependent analysis is commonly used in a first-pass analysis of samples. The entire HPLC/MS analysis is automated once the scientist loads a sample into the autosampler tray. The number of injections per vial and the injection volume can be controlled by various instrument programs. The time-consuming data analysis process can also be automated to some degree; indeed the scientist can load a sample in the evening and data printouts are waiting in the printer bin when the scientist returns the next day. With modems and networking, progress can be monitored and analyses interrupted remotely if necessary to avoid waste of valuable samples.

As an example, a routine for sequencing peptides would be designed to select an ion for MS/MS, based on ion current intensity. As carried out on a TQ instrument, the mass spectrometer would be set-up (i.e. tuned) to operate with Q2 at a constant argon pressure of 3 mTorr. The offset on Q3 is increased to compensate for the dampening effect of this gas. No fragmentation is observed from such low-energy collision with the gas because the ions during a normal MS scan are not accelerated into the collision gas. However, once the instrument control language (ICL) procedure selects an ion for MS/MS, then the Q2 offset is increased as a function of the $m/z$ value selected for MS/MS. More energy for fragmentation is required for higher $m/z$ values than smaller, but less for higher charge states than lower ones, because the energy barrier to fragmentation is lowered by Coulombic repulsion when more than one charge is present. For this automated MS/MS process the instrument is not optimized for a specific ion of interest and so Q2 offset energy is increased slightly during three consecutive MS/MS scans such that the final summed MS/MS spectrum is a composite of MS/MS scans carried out all on the same ion but at various energies. This rotation of energy compensates for the lack of operator input during the process and produces readily interpretable spectra. Once the three MS/MS scans for the selected ion are acquired, the ICL procedure returns the mass spectrometer to full scan or simple MS mode and the process of ion selection begins again. The ion just selected for MS/MS goes into a list of ions to prevent it from being immediately selected again should it prove to be still the most intense ion in the first scan after switching back to MS mode. In this manner, a 100 MS/MS spectra can be acquired in a single LC run. On an IT where scans are of the order of milliseconds rather than seconds, many more MS/MS spectra can be acquired per LC run. This advantage can be of value when seeking to get as complete a coverage as possible on the peptides present in a tryptic digest. Additional information and ICL routines can be found at the World Wide Web site: http://depts.washington.edu/~ruedilab/aebersold.html.

4.3 Managing Instrument Time

Mass spectrometers, being so-called universal-type detectors, rarely sit idle once installed. If the instrument is easy to use and delivers the expected results then chemists and biologists will keep the instrument busy. Mass spectrometers tend to be set-up in three broad categories of user: the single-operator instrument, which is usually a more complicated design or usage; the open-access instrument, for multiple users who are often the least experienced; and the multiple-operator instrument, which is used by many experienced users. In the last 10 years mass spectrometers have become more user-friendly to the point where instruments are more often sold today to chemists, chromatographers or biologists with no prior experience in setting them up. This ease of use has made the open-access laboratory and the multiple-user set-up possible where before specialists were needed just to maintain the instrument. Many open-access instruments are usually maintained by an analytical department, or other departments that are heavy users of MS instrumentation simply hire at least one person trained in MS. Manufacturers have made interfacing to a mass spectrometer easy for the novice by using computer software such as Windows NT, with which most people are familiar. For many MS instruments, operation may be as easy as any other laboratory instrument, such as a gas chromatography, HPLC or UV–visible spectrophotometer.

5 QUANTITATION OF PEPTIDES BY ELECTROSPRAY IONIZATION/MASS SPECTROMETRY

5.1 Analysis of Peptides in Physiological Fluids

Analysis of trace levels of drugs in urine by automated procedures that avoid SPE is of particular interest in the pharmaceutical sciences. Benefits to direct sample analysis over SPE include a decrease in sample preparation
time and a reduction in nonspecific losses that can occur during SPE. Although SPE produces adequate sensitivity for most studies, it is time-consuming and costly. Methods that allow peptides to be analyzed directly from plasma or urine are also of interest because of the low half-life of most peptides in physiological fluids. For a small peptide such as thymopentin (Arg-Lys-Asp-Val-Tyr), it can be as low as 30 s. The limited bioavailability of orally administered peptides is due in large part to enzymatic and acid hydrolysis in the gut and stomach. Resis-
tance to hydrolysis may be improved by modification of the amino- and carboxyl-termini. Even so, methods that provide rapid processing of peptides in physiological fluids for analysis are needed for pharmacokinetic studies where the concentration of peptides is low at the start of extraction.

“Column-switching” protocols have been employed where analytes in crude mixtures need to be analyzed directly by MS. Such a protocol avoids SPE preparation by relying on interaction of the analyte with the stationary phase while most endogenous components are washed to waste. Selective chromatographic conditions retain the analyte until sufficiently clean and then pneum-
atically switched valves redirect flow from waste to MS for detection. Such techniques have been demonstrated for the analysis LSD analogs and metabolites in urine. They allow clean-up with no precolum sample preparation and direct quantitation by MS methods.

When coupled with HPLC separations, the ionization technique of choice for charged analytes such as peptides is ESI. However, the presence of alkali salts and other nonvolatile compounds in a physiological sample degrades sensitivity by competing efficiently with the analyte for available ESI current. Thus, it is important to remove as many of the nonanalyte components as possible prior to ESI/MS analysis. For MS detection with ESI, clean-up is necessary because the salts and urea present in urine decrease MS performance by physically occluding the atmospheric inlet and coating the lenses used to complete desolvation and then focus ions. An additional problem with salt in a sample is that alkali metals such as sodium are efficiently bound to carboxylic acid moieties, decreasing the relative amount of [peptide + H]^+ available for detection by single or multiple ion monitoring of a narrow m/z range around the [peptide + H]^+ value. With such orthogonal techniques as ion exchange and HPLC coupled on-line to MS it is important that the ion exchange cycle be followed by thorough rinsing to avoid such problems as ion adduction to analytes. The following study demonstrates the use of a “column-switching” chromatography system for automated, on-line detection of peptides in urine by ESI/MS.

5.2 Tandem Liquid Chromatography/Mass Spectrometry Quantitation of Peptides in Urine

Prior to use, refrigerated urine is treated with triflu-
oroacetic acid (TFA) to give a final concentration of 1% and a pH of approximately 3.0. Excess endogenous materials precipitated by TFA are removed by centrifugation at 3000 rpm for 30 min. The supernatant from acidified urine is filtered through 0.2-µm Anodisc. For ion-exchange HPLC, a 1 M potassium phosphate stock solution filtered through a 0.2-µm Anodisc filter is used to prepare mobile phases A (75 mM) and B (700 mM) by dilution. Before final dilution with HPLC-grade water, acetonitrile is added to A and B so that the final concentration is 7.5% and the pH is adjusted to 3.5 with 85% phosphoric acid. For reversed-phase HPLC, mobile phases C and D contain 0.05% TFA with 2% and 60% methanol, respectively. Solutions of IRI-695 (N-acetyl-L-
arginyl-L-prolyl-L-aspartyl-NH-isobutyrl) are prepared at 0, 2, 10, 100, 500, and 1000 ng mL\(^{-1}\) in water or urine and each contains 400 ng mL\(^{-1}\) of IRI-959 (N-acetyl-L-
arginyl-L-prolyl-L-aspartyl-NH-isopentyl).

A diagram of the column-switching apparatus is shown in Figure 2. Pump one (P1) is a Waters Model 616 (Division of Millipore Corp., Milford, MA, USA) capable of delivering four different mobile phases; pump two (P2) consists of two Shimadzu Model LC-10AD units linked to perform a linear gradient; and pump three (P3) is a single Shimadzu Model LC-10AD. Additional instruments include a Model 717 autosampler, a Model 600S controller, and two Model 486 tunable absorbance UV detectors. Both UV detectors are connected to Hewlett-Packard 3395 recording integrators (Palo Alto, CA, USA). Two Rheodyne (Cotati, CA, USA) high-pressure automated six-port switching valves are used with pneumatic actuators engaged at 80 psi. The HPLC columns are as follows: for cation exchange, a Spherisorb Phase Sep SCX, 250 mm × 4.6 mm i.d. column with 5-µm particles (Norwalk, CT); for trapping prior to reversed-
phase HPLC, a YMC S3 ODS, C18, 50 mm × 4 mm i.d. column with 3-µm particles (Wilmington, NC, USA); and for analytical reversed-phase separation, a YMC Basic S5, 250 mm × 2 mm i.d. column with 5-µm particles. All columns are kept at 35 °C inside a Shimadzu CTO-10A column heater.

The mass spectrometer is operated at unit resolution in multiple ion monitoring mode, scanning continuously during tandem liquid chromatography/mass spectrometry (LC/MS). The range scanned for analyte (IRI-695; [M + H]^+ = 485) and internal standard (IRI-959; [M + H]^+ = 499) is set at [M + H]^+ ± 1.0 amu. One complete scan of the [M + H]^+ value for both peptides took 2 s. Chromatographic separations are monitored by UV absorption at 210 nm after the ion-exchange column...
Figure 2 Solvent flow diagram for the four cycles of orthogonal ion-exchange chromatography/reversed-phase HPLC (LC/LC/MS) used to clean up peptides in raw urine prior to on-line analysis by ESI/MS. MPA–MPD refer to mobile phases A–D.
and after the analytical column. Figure 2 shows the four stages of one LC/LC/MS cycle. Pump P1 maintains flow through the ion-exchange column at 1 mL min\(^{-1}\) through all four stages and delivers mobile phases A, B and C. Pumps P2 and P3 deliver mobile phases C and D at 0.25 mL min\(^{-1}\). Pump P3 provides a constant flow of mobile phase D to the mass spectrometer with a post-column splitter sending one-third of that to the ESI source and two-thirds to the second UV detector.

5.3 Discussion

This LC/LC/MS method consists of four cycles (Figure 2). The only sample preparation prior to injection onto the cation-exchange column involved acidification of raw urine followed by centrifugation. This ensures that peptides are at an acidic pH sufficient for cation exchange to work efficiently and removes endogenous components that flocculate during refrigeration. During cycle 1 (Figure 2), peptides in urine are loaded on a cation-exchange column and washed just as during SPE preparation. After washing the column to remove as much endogenous material as possible, the peptides are transferred directly by a gradient of increasing potassium phosphate concentration to a reversed-phase trapping column. The trapping column and analytical column avoid contamination by most of the endogenous urinary waste because the valve between the cation-exchange and trapping column does not flow directly toward the trapping column until immediately prior to gradient elution of the peptides.

Valve switching times were determined by monitoring UV absorbance of peptides after injecting a 0.1 mg mL\(^{-1}\) standard solution. The first UV detector, located after the cation-exchange column (Figure 2), allows valve switching times to be optimized so that most UV-absorbing material goes to waste rather than to the trapping column. Based on the area under the curve, 90% of the UV-absorbing material goes to waste prior to elution of the peptides. The isopentyl group of IRI-959 ensures chromatographic resolution from IRI-695, which contains an isobutyl group instead of the isopentyl group. Peptides IRI-695 and IRI-959 were resolved chromatographically on both the cation-exchange and reversed-phase columns.

An initial concern with ESI/MS detection was the high potassium phosphate concentration needed to carry out ion exchange. Any peptide adducts would reduce the limit of detection of the method by reducing the \([M + H]^+\) species available for detection. In solution, peptides readily form adducts with potassium and/or phosphate ions that are easily observed by ESI/MS. However, neither potassium nor phosphate adducts to the peptides were observed by ESI/MS. One other concern prior to the study was the high content of urea in urine. It was expected that the chromatography would be degraded and the atmospheric pressure inlet clogged because the average concentration of urea in urine is 330 mM. To test whether or not urea would have an effect on peptide recovery and cause the mentioned physical problems, IRI-695 and IRI-959 were spiked into a 330 mM urea solution and analyzed by LC/LC/MS. This high concentration of urea alone did not change the recovery of peptides, nor did it cause any other obvious physical problems with equipment, which suggests that most of the urea was removed during the cation-exchange cycle (data not shown).

Ruggedness of the columns was determined by multiple urine injections. Approximately 100 urine injections were done without any change of HPLC columns. Inclusion of the internal standard in each sample provided a measure of column performance. Any change in chromatographic resolution could be noted and changes made. However, during the course of developing this method the reproducibility of retention times proved the method to be rugged. The limit of detection for IRI-695 in water was 2 ng mL\(^{-1}\) and in urine 10 ng mL\(^{-1}\). Performance of the ESI-heated capillary used in desolvation of analyte did not degrade over the course of 100 analyses. Detection of IRI-695 in urine by LC/LC/MS was linear from 10 to 1000 ng mL\(^{-1}\) (Figure 3) and sensitive, with a limit of detection of 10 ng mL\(^{-1}\). The LC/ESI/MS process is completely automated and chromatographic fidelity is maintained after over 100 separations without a change of column.

6 CHIRAL ANALYSIS

6.1 Chiral Amino Acid Analysis

Characterization of peptides for an investigational new drug or new drug application submission to the FDA
requires that all impurities above 0.1% level be identified. It is expected that most impurities will be related to the product chemically. For peptide drugs this means that the related substances may be oxidized forms, truncated forms resulting from degradation of the parent peptide, the parent peptide with protecting groups intact from the synthesis or simply a chiral impurity. Using reversed-phase HPLC, most related substances can be separated from the parent peptide and purified for characterization. In an automated setting, impurities might be characterized on-line with some sort of data-dependent MS/MS ICL procedure. If this is not practical because of limited sample, then scale-up for purification is necessary.

Related substances that are isobaric with the peptide drug are likely to be stereoisomers where one or more amino acid is in the D-amino acid configuration rather than the bioactive L-amino acid form. Substitution of a D-amino acid for an L-amino acid may result in a biologically inactive drug or, worse, impart some sort of toxic property not present in the all-L-amino acid peptide. Thus, chiral analysis of a peptide drug and any related substances is an important part of the overall characterization process before submission to the FDA. Methods that provide rapid and accurate assessment of chiral purity have been developed and will be reviewed in sections 6 and 7.\textsuperscript{38,39}

6.2 Liquid Chromatography/Mass Spectrometry Chiral Purity

An LC/MS method that allows fast determination of the chiral purity of a peptide is described that involves hydrolysis in deuterium-enriched HCl (DCl)–deuterium-enriched acetic acid (DOAc) followed by derivatization with a chiral reagent (Scheme 1) to create diastereomers that can be separated and quantitated by LC/MS. During peptide hydrolysis the ratio of D-/L-amino acids present in the original peptide can change significantly by acid racemization through an enol intermediate.\textsuperscript{38} Peptide hydrolysis in deuterated solvents labels amino acids that racemize during hydrolysis with one deuterium at the chiral center. Racemized amino acids, labeled with deuterium, can be distinguished from non-racemized amino acids by MS because of the increase in molecular weight by one mass unit. Labeling with 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide (FDAA) allows the five L-amino acids found in a control peptide thymopentin and all possible D-amino acid pairs to be separated in one chromatographic experiment on a conventional reversed-phase column.\textsuperscript{38} All peptides were hydrolyzed for 18 h at 130°C in 1:1 HCl–HOAc or DCl–DOAc. Hydrolyzed peptides were lyophilized and then dissolved in 400 µL of water. To this was added 100 µL of 1 N NaHCO\textsubscript{3} and then 200 µL of 38.7 mM FDAA in acetone.

The solution was vortexed and incubated at 40°C for 1 h. Reactions were quenched by 50 µL of 2N HCl. For LC/MS analysis, samples were diluted 1:10 with solvent A described below. Amino acids labeled with FDAA are referred to as 1-fluoro-2,4-dinitrophenyl-5-L-alanine-labeled or DNPA-amino acids in the text.

\begin{center}
\textbf{Scheme 1} Derivatization of an amino acid with FDAA amide after peptide/protein acid hydrolysis. The derivatization reaction produces a diastereomer, as in this example with alanine, that becomes 1-L-alanine-2,4-dinitrophenyl-5-L-alanine amide or DNPA-alanine.
\end{center}

HPLC separation was by linear gradient using a YMC basic 2.0 × 250-mm column with post-column flow splitting. Two-thirds of the flow was split for UV detection at 340 nm and one-third was split for MS detection. Solvent A was 0.05% TFA, 1.0% methanol and 5.0% acetonitrile and solvent B was 0.05% TFA, 1.0% methanol and 60.0% acetonitrile. Alternatively, a 10 mM ammonium formate (pH 5.2) solvent system was used that was prepared with the same methanol and acetonitrile concentrations as per solvents A and B above but without the TFA. This was done by bringing solvents A and B to volume (1.0 L total each) using 10 mM ammonium formate instead of water. The flow rate at the pump was 0.25 mL min\textsuperscript{-1} and in 20 min the gradient went from initial conditions of 80% A–20% B to 20% A–80% B. For LC/MS, flow from the column was 0.083 mL min\textsuperscript{-1}, such that with the coaxial sheath (methanol) the total flow was 0.183 mL min\textsuperscript{-1} and +3.0 kV was applied for ESI. When a single amino acid was suspected of being in the D-amino acid form then the mass spectrometer was operated at unit resolution and scanned ±5.0 units around the ion of interest. To increase sensitivity at unit resolution, only one ion of interest was scanned per LC/MS run. Alternatively, single ion monitoring (e.g. for [DNPA-lysine + H]\textsuperscript{+} = 393)
was also carried out to observe simultaneously each of the five amino acids in thymopentin. Controls using D- and L-amino acids found in thymopentin were used to establish order of elution. The relative chiral purity of each D-/L-amino acid pair was calculated from the integrated area of extracted ion chromatograms (Figure 4).

6.3 Discussion
The method has been used to establish the chiral purity of a thymopentin-related substance. The unknown was originally present at less than 0.1% level relative to thymopentin. From proton nuclear magnetic resonance data it was suspected that the impurity contained D-Asp or D-Val and possessed a second lysine residue. Three standards were synthesized for comparison: Arg-Lys-Lys-Asp-Val-Tyr; Arg-Lys-Lys-D-Asp-Val-Tyr; and Arg-Lys-Lys-Asp-D-Val-Tyr. After processing through the above protocol, it was concluded that the impurity was composed of only L-amino acids. The impurity then had to be isolated for sequence analysis by MS and Edman chemistry. It was found to have the sequence Arg-Lys-Lys-Asp-Val-Tyr. Note that Figure 4 shows the separation of all D- and L-amino acids involved in this study. A more comprehensive study showed that all L-amino acids and their D-amino acid pairs could be separated in a single LC/MS run.\(^{(38)}\)

7 COMPARATIVE TANDEM MASS SPECTROMETRY

7.1 Background on Collision-induced Dissociation of Peptides
Interpretative CID routines like SEQUEST compare observed CID spectra of peptides to artificial spectra of peptides found in sequence databases and generate a list of most likely matches. Such routines work very well, but lack the ability to incorporate chemical information found in the peptide sequence; the artificial CID spectrum created by a computer routine will be a series of \(m/z\) values of equal intensity. An objective comparison of the tendency of a series of related peptides to generate specific fragments can be used to yield information useful in screening peptide drugs for specific impurities. This section will provide an example of such a comparative analysis.

Before preceding it is necessary to review briefly the fragment ion nomenclature used by mass spectrometrists to describe fragment ions used for sequence analysis. For sequence analysis, proteins are processed by proteolysis to peptides, which are then analyzed easily by electrospray ionization/tandem mass spectrometry (ESI/MS/MS). Trypsin is often used because proteins tend to have numerous cleavage sites for trypsin (i.e. Lys and Arg), but also because peptides produced by tryptic digestion of a protein have either lysine or arginine at the carboxyl-terminus and thus with a charge fixed at the carboxyl-terminus will produce a nearly complete series of y-ion fragments. Peptide fragments that retain charge on the carboxyl portion are termed y-ions and on the amino-terminus b-ions (Figure 5a).\(^{(46)}\) An example of how fragment ions are calculated for the pentapeptide Arg-Lys-Asp-Val-Tyr is shown in Figure 5(b).

Data accumulated over the years allow certain predictions to be made about the CID spectrum of a peptide based on the amino acid sequence (i.e. the

---

**Figure 5** (a) Peptide fragment ion nomenclature as suggested by Roepstorff and Fohlman.\(^{(49)}\) (b) Example of calculating b- and y-ion fragments for a peptide (Tp-5 or thymopentin) from nominal residue masses.
An alternative to the LC/MS chiral method presented above was devised using comparative MS/MS of synthetic standards. Just as in section 6 above, it was of interest to know when a D-amino acid isomer of the peptide Arg-Lys-Asp-Val-Tyr (RKDVY) appeared during stability studies or as a result of production procedures. The study used the series of peptides based on the peptide RKDVY, where each L-amino acid was replaced with a D-amino acid such that there were six peptides for comparison. The study compared the CID of each of six peptides using electrospray ionization/triple quadrupole tandem mass spectrometry (ESI/TQ/MS/MS) and electrospray ionization/ion trap tandem mass spectrometry (ESI/IT/MS/MS) and looked at both the 1+ and 2+ ions for each of the peptides. It was shown that peptides in this isomeric series produced fragments that could be correlated with unique structural features of individual peptides.

### 7.2 Chiral Analysis of Peptides by Tandem Mass Spectrometry

CID spectra of the following peptide 1+ and 2+ ions were compared: Arg-Lys-Asp-Val-Tyr, D-Arg-Lys-Asp-Val-Tyr, Arg-D-Lys-Asp-Val-Tyr, Arg-Lys-D-Asp-Val-Tyr, Arg-Lys-Asp-D-Val-Tyr and Arg-Lys-Asp-Val-D-Tyr. All peptides (1.5 pmol µL⁻¹) were introduced into an ESI source by direct infusion at 3 µL min⁻¹ in an acidic solution. Low-energy CID spectra were obtained on a Finnigan lcq 7000 TQ mass spectrometer and a Finnigan lcq IT mass spectrometer (San Jose, CA). For comparison, CID spectra were averaged for 1 min and collision energies were optimized for one of four sets of experiments: triple quadrupole collision-induced dissociation (TQ/CID) of 1+ ion (680 m/z), TQ/CID of 2+ ion (340 m/z), ion trap collision-induced dissociation (IT/CID) of 1+ ion and IT/CID of 2+ ion. Specifically the fragment ions b3 (400 amu) and b4 (499 amu) were compared. For graphical comparison, the ratio of the observed intensity of b3/b4 ions in each isomer was calculated and all values normalized to the same ratio for the all-L-amino acid peptide. This type of data analysis allows an unbiased assessment of the tendency of a given isomer to form the fragment ions b3 and b4. As seen in the following discussion, when bar graphs of such data are used for comparison an objective analysis can be done even by a novice.

### 7.3 Discussion

Some general trends are apparent when comparing the IT and TQ/CID of peptides. The most obvious is the reduction in complexity in the IT data. Fewer fragment ions are observed with the IT/CID of a 1+ ion (Figure 7a, c) than with the TQ (Figure 7b, d). This is likely due...
Immonium ions are diagnostic of the amino acids present in a peptide. Amino acids except leucine/isoleucine, which are isobaric, provide a unique mass for each of the 21 possible amino acids when D-amino acids near the amino-terminus are substituted for L-amino acids. The CID of the 1+ ions, but not the 2+ ions, showed marked differences between isomers. The trend for the 1+ ions is shown in Figure 8. The lack of a trend in the fragments from the 2+ ions is likely to be due to Coulombic repulsion. A peptide with two charges requires less energy for fragmentation than a peptide with only one charge due to Coulombic repulsion. The repulsion between two charges on one peptide molecule lowers the energy barrier to fragment ion formation. This effect likely prevents observation of any subtle differences between isomers that are apparent with the 1+ ions. Such subtle differences between isomers are observed in the 1+ ion series on both instruments.

Both instruments showed differences in fragmentation when D-amino acids were substituted for L-amino acids near positions 3 and 4 of RKDVY, but the IT 1+ ion data showed a more prevalent trend than the TQ 1+ ion data. Substitution of D-amino acids near the amino-
and carboxyl-terminii did not affect fragmentation of the b3/b4 ratio. This is expected, based on the tendency of this given peptide sequence (i.e. chemistry) to form intense b3 and b4 ions relative to all the other possibilities. The most obvious trend is in the IT 1+ ion data (Figure 8a) where the D-Val-thymopentin isomer was the most likely to form the b3 ion relative to the b4. The D-Val-thymopentin isomer likely decreases the energy barrier to the formation of this b3 fragmentation pathway via a specific steric constraint that promotes the formation of the putative five-membered ring between the aspartic acid side chain and the “b3” amide bond (Figure 8a). Recall that in an all-L-amino acid peptide each amino acid in the sequence points away from the backbone in an alternating fashion. As soon as one D-amino acid is introduced, then the adjacent L- and D-amino acids will have side chains on the same side of the amide bond backbone rather than the normal where side chains project to one side or the other in an alternating fashion down the backbone. Interestingly, the 1+ ion CID data from the TQ does not show the same strong trend toward the D-Val-isomer (Figure 8b). The D-Val isomer is still the most likely to produce the strongest b3/b4 ion ratio, but now the series dips at the D-Lys isomer. In this case the D-Lys isomer must interfere with the formation of the five-membered ring by the L-Asp side chain and the “b3” amide bond. Given the longer time frame of the CID experiment in the TQ the D-Lys isomer must allow stabilization of a structure that prevents facile cleavage of the b3 amide bond. Whatever the physicochemical explanation, such graphical displays of data allow even the novice to find trends. In this case comparative MS/MS analysis on either instrument shows a definite influence from the substitution of an L-amino acid for a D-amino acid. As such, these comparative analyses could be used as a less labor-intensive method to screen impurities in libraries than the chiral analysis presented in section 6. Unless there is a compelling reason to use TQ/MS, then IT/MS analysis would offer the advantages of faster scans, lower instrument start-up costs and less complex CID data to interpret.

8 NONCONVENTIONAL MASS SPECTROMETRY

8.1 Noncovalent Complex Analysis

One area of MS that is nonconventional but appropriate for biological studies is the study of noncovalent complexes. In the past 10 years a number of articles have been published describing this research. Basic to these studies is the use of soft ionization techniques like ESI to transfer noncovalent complexes from solution to the gas phase. Argument continues about whether or not the ionization process significantly perturbs the system under study. However, a number of studies would indicate that when proper controls using techniques such as nuclear magnetic resonance and circular dichroism are conducted, then the results can be trusted. In fact, one of the earliest studies showed that the dissociation constant \( K_d \) for a series of enzyme inhibitors had the same relative affinities in the gas phase as in solution. \(^{45}\) Thermal denaturation of RNAse S in the gas phase also correlated with the change in enthalpy (\( \Delta H \)) of dissociation measured by traditional calorimetry. \(^{46}\) As a last application an example will be presented showing that the thermal denaturation of DNA measured in a manner analogous to that for RNAse S exhibits a melting temperature \( T_m \) close to that shown by circular dichroism.

Guanine-rich DNA can be found in the telomeric region of certain chromosomes. \(^{47}\) When removed from the chromosome and analyzed as small oligonucleotides these guanine-rich sequences form quadruple-stranded complexes in the presence of cations such as \( K^+ \), \( Ca^{2+} \), and...
and Na⁺, but dissociate into single-stranded DNA in the absence of cations. Proton nuclear magnetic resonance, circular dichroism and electrophoresis have been used to study the cation-dependent thermal stability of quadruplex DNA. Also, it has been shown previously that these quadruplex–cation structures and more common duplex structures can be transferred intact into the gas phase. The following example shows that on-line thermal denaturation of the quadruplex–cation structures can be used to estimate the $T_m$ of such non-covalent structures by ESI/MS.

### 8.2 Thermal Denaturation of Noncovalent Complexes

Liquid-phase thermal denaturation was conducted in 60 cm of an 80-cm length of 50-µm i.d. × 180-µm o.d. fused-silica capillary wrapped in heating tape, with segments of about 8 cm at the ESI sources and 12 cm at the syringe remaining unheated. Temperature was measured with a thermal couple placed inside the heating tape and next to the fused-silica capillary. For thermal denaturation studies the capillary was filled with sample and incubated at a given temperature for 10 min prior to acquiring ESI data. After the thermal equilibration period the syringe pump was turned on and the sample infused at 0.5 µL min⁻¹. The thermally equilibrated sample was pushed out of the syringe using distilled, deionized water. The synthetic oligomer for the study had the sequence d(CGCGGGGCGG). The single-stranded oligomer was prepared for ESI/MS by HPLC purification to remove low-molecular-weight impurities and residual salt. Quadruplex-DNA was prepared in the presence of 10 mM sodium phosphate (pH 7.6) containing 0.1 mM ethylenediaminetetraacetic acid (EDTA) from single-stranded d(CGCGGGGCGG) according to established protocols. For MS a home-built SQ instrument was used that was assembled from Extrel components and consisted of a nozzle-skimmer atmospheric pressure inlet followed by an RF-only quadrupole surrounded by a cryopumping surface. The front plate was held at ambient temperature and the lens was at 1.0 kV. A counter-current stream of nitrogen gas at ambient room temperature was used to assist desolvation and a co-axial stream of SF₆ within the ESI source prevented discharge from the aqueous solutions. ESI was carried out in negative ion mode.

### 8.3 Discussion

At room temperature in 10 mM sodium phosphate (pH 7.6) and 0.1 mM EDTA, ions corresponding to both single-stranded d(CGCGGGGCGG) (i.e. G₄) and quadruplex G₄ (i.e. (G₄)₄) were observed at a low nozzle-skimmer bias of −150 V (Figure 9a): so-called

---

**Figure 9** Thermal denaturation of quadruplex DNA ((G₄)₄) in solution at room temperature and low nozzle-skimmer bias (a) analyzed by negative ion ESI/MS. The (G₄)₄ DNA dissociates at high temperature (b) or high nozzle-skimmer bias (c) into single-stranded DNA (G₄).
noncovalent friendly conditions on this particular instrument. The \((G4)_4\) species could be converted largely to the single-stranded G4 by raising the nozzle-skimmer bias to \(-250\) V (Figure 9b) or by raising the solution temperature to \(90^\circ\)C (Figure 9c). This simple result agrees with circular dichroism studies carried out under identical conditions of ionic strength and ionic species present, which showed that the quadruplex DNA had a \(T_m\) of \(90^\circ\)C. A study of a related quadruplex \([d(CGCGGGGCG)]_4\) showed that it had a \(T_m\) of approximately \(80^\circ\)C. This measurement also agreed with circular dichroism studies and the chemical intuition that one less guanine would lower thermal stability. Although such studies are decidedly difficult to carry out, a number of pharmaceutical companies have made a significant investment in using ESI/MS analysis of noncovalent complexes to screen ligand libraries as a guide prior to further drug development.

9 CONCLUSIONS

As can be seen by the diversity of applications provided, the use of MS in the field of pharmaceutical sciences is vast and a single chapter cannot adequately address all the issues at hand. It covers fields as diverse as protein chemistry, combinatorial chemistry, and clinical chemistry. This article sought to address some of the more common uses of MS in pharmaceutical sciences by presenting novel approaches to quantitation of peptides in urine, chiral analysis of peptides, comparative MS/MS and thermal stability of noncovalent complexes. Each of these single areas constitutes a field of research in itself. So it is hoped that the reader gains enough insight from the discussions to have a basic understanding of each field of study presented here.

The future of MS in pharmaceutical sciences promises to include more often the use of Fourier transform ion cyclotron resonance/mass spectrometry (FTICR/MS). An excellent review of this technique was published recently and so the fundamentals of FTICR/MS operation will be left for the reader’s initiative. The reason why FTICR/MS is likely to become so important are fourfold: high resolution (e.g. 1 000 000 @ 1000 amu as \(m/\Delta m\) at 50% peak height); high mass accuracy (at least 1 ppm @ 1000 amu; i.e. for 1 ppm @ 1000 amu the mass can be measured accurately to the thousandth place as 1000,001 amu); high sensitivity (zepto- to attomoles for small molecules); and broad dynamic range; all these advantages are combined in one instrument. Additionally, all of these benefits can be carried out on-line with HPLC or capillary electrophoresis and with either ESI or MALDI ionization. The possibility to make accurate \(m/z\) measurements to 0.1 ppm (@ 1000 amu) should make it feasible to identify proteins in sequence databases based on the accurate mass tag provided by a single peptide molecular weight. This advantage will allow the identification of analytes in defined libraries without time-consuming MS/MS procedures and promises to increase significantly the rate at which samples can be screened.

Nuclear Magnetic Resonance Spectroscopy in Pharmaceutical Analysis

Brian Dawson

1 INTRODUCTION

The nuclei of atoms with an odd number of protons, neutrons, or both, have an intrinsic nuclear spin. The spinning of charged particles – the circulation of charges – produces a magnetic moment along the axis of spin. The simplest nucleus possessing a spin is the proton – the nucleus of the hydrogen atom. If hydrogen atoms are placed in an external magnetic field, their magnetic moments, according to quantum mechanics, will become aligned in one of two ways – with or against the external field. For hydrogen, the more stable alignment is with the field and energy must be absorbed to “flip” the proton over to the less stable alignment against the field. The amount of energy needed to flip the proton depends on the strength of the external field: the stronger the field, the greater the energy required to produce the flip. The energy required corresponds to electromagnetic radiation in the radiofrequency (RF) range. The observation frequency is given by Equation (1)

\[ v = \frac{\gamma H_0}{2\pi} \]  

(1)

where \( v \) = frequency, in cycles per second; \( \gamma \) = a nuclear constant (the gyromagnetic ratio) and \( H_0 \) = strength of the static magnetic field, in tesla. When the nucleus is irradiated at the proper frequency, absorption occurs, followed by the nuclei re-emitting the RF radiation to return to the lower energy state. This process gives rise to a signal and the spectrum arising from this signal is called an NMR spectrum. The frequency at which a nucleus absorbs depends on the magnetic field that it feels, and this effective field strength is not exactly the same as the applied field strength. The effective field strength at each nucleus depends on its environment – the electron density, closeness of other nuclei, etc. – and hence in each case a slightly different applied frequency is required in order for absorption to take place. Thus each different nucleus will give rise to its own signal.

There are two basic NMR spectrometer designs – continuous wave (CW), and pulsed or Fourier transform
(FT). CW spectrometers have low-field water-cooled electromagnets which consume large amounts of electricity. The newer Fourier transform nuclear magnetic resonance (FTNMR) spectrometers use liquid-helium-cooled superconducting magnets which consume very little electrical power, but require relatively expensive cryogens (liquid nitrogen and liquid helium) to keep them working. Although CW spectrometers are perfectly suitable for many routine applications, they have largely been replaced by the higher-field pulsed FTNMR instruments.

Because the energy difference between the nuclei aligned with and against the field is small, the number of nuclei in each spin state are almost equal. There is, however, a slight excess of spins in the more stable alignment (of the order of 1 in $10^5$ for protons at 200 MHz). It is the signal from this excess which gives rise to the NMR signal, thus explaining the relative insensitivity of this technique. However, over the last 20 years, the field strength (and thus sensitivity) has grown by leaps and bounds. Even the more routine modern instruments (300–500 MHz) are capable of producing good quality proton NMR spectra with microgram amounts of small drugs and related compounds. Lower field spectrometers are useful for acquiring routine spectra from smaller molecules where sample quantity is not limited. Higher-field magnets (currently up to 18.8 T, with a proton frequency of 800 MHz) are required for more demanding research applications.

When regulatory laboratories are performing analyses of pharmaceutical products, the analytical techniques used must meet a number of strict criteria. Besides being sufficiently sensitive, they must be highly selective, reproducible and suitable to give qualitative and, in many cases, quantitative analyses. Other desirable features for more routine pharmaceutical methods include that they require the minimum amount of sample pretreatment and that they be able to handle mixtures of substances without prior separation. As will be seen from the following discussion, NMR spectroscopy meets all these requirements and is becoming more and more important for identification of unknown substances, as well as for routine analyses, in many pharmaceutical laboratories throughout the world.

Organic compounds, including pharmaceuticals, are composed of relatively few chemical elements (hydrogen, carbon, oxygen, nitrogen, and phosphorus, as well as the halogens and sometimes metals). Each of these elements has one or more isotopes that may be detected by NMR experiments. However, due to low natural abundance and/or low relative sensitivity of the nuclei, many of these elements are not routinely studied. Those that are commonly studied include hydrogen ($^1$H), carbon ($^{13}$C), fluorine ($^{19}$F) and phosphorus ($^{31}$P). In order to study the structure of larger macromolecules (proteins, for example), it is usually necessary to enrich (i.e. label) the samples with $^{13}$C, $^{15}$N and sometimes $^2$H (see section 2.3.2.5).

2 ANALYSIS OF DRUGS

2.1 Sample Types

The most important role NMR plays in pharmaceutical analysis is its use in elucidation and/or confirmation of structures for drug-related substances. This would include the drugs themselves, either as raw materials or in formulations. NMR has also been used extensively to study drug impurities including solvents, synthetic precursors, synthetic intermediates, and decomposition products. In the case of natural products NMR may be used to determine the identity of co-extractives. Another key area where NMR has proved to be invaluable is in the study of drug metabolism where it has been used for identification and quantification of many metabolites.

In addition to the high-resolution solution NMR techniques, several other magnetic resonance methodologies are sometimes used in pharmaceutical studies. Solid-state NMR has been used to study polymorphism of drug powders. Micro-imaging NMR may be used to study dissolution of drug tablets. The use of whole-body imaging NMR is a very powerful tool for clinical diagnosis. Extensive discussion of these areas is beyond the scope of this article.

2.2 Sample Preparation

The methods used to prepare the pharmaceutical samples for NMR analyses depend on the source of the sample and the information required. Procedures range from simple dissolution to complex extraction and derivatization reactions which must be done under very stringent conditions.

For the simplest case of “pure” drug raw material from a small pharmaceutical, a suitable quantity (usually a few milligrams) of the sample is dissolved in a deuterated NMR solvent. The choice of solvent depends on the solubility and stability of the drug. Commonly used deuterated solvents include chloroform ($\text{CDCl}_3$), water ($\text{D}_2\text{O}$), dimethylsulfoxide ($\text{DMSO-}d_6$), methanol ($\text{CD}_3\text{OD}$) or a mixture of chloroform and methanol ($\text{CDCl}_3$/CD$_3$OD). The amount of sample used depends on the quantity of sample available, the field strength of the spectrometer and the type of NMR experiments to be performed (see section 2.3).

In cases where the pharmaceutical product is a mixture, such as in tablets or elixirs where the drug is mixed with excipients such as sugars or starch, sample preparation
methods depend on the nature of the components. It is often possible to choose a solvent which will dissolve only the drug, leaving the other excipients behind, or to choose two immiscible solvents where the drug will go into one solvent while the excipients go into the other. For example, deuterochloroform will extract many drugs from formulations where the excipients are sugars, since sugars will not dissolve in this solvent but may be taken up in water. In many situations, however, this simple procedure will not work and one must use the chemical characteristics of the drug to separate it from its excipients. Drugs may conveniently be divided into four general categories – acidic, basic, amphoteric and neutral. Each category has different partition coefficients between aqueous and immiscible organic solvents. The hydrogen ion concentration in the aqueous phase, which varies with pH, affects the ionic state or polarity of the drug, depending on the polar substituents present. It is often possible to separate drugs from the different classes from each other or from other organic compounds by proper adjustment of the pH. For example, if the aqueous solution is made acidic, organic solvents may be used to remove acidic and neutral components. On the other hand, if the aqueous phase is made basic, basic and neutral components may be extracted with organic solvents. For amphoteric drugs such as morphine, the pH must be adjusted to its isoelectric point before extraction is possible. At this pH, the drug exists in a nonpolar or nonionized form, making it more soluble in appropriate organic solvents than in water. It is possible to isolate or remove neutral drugs or other organic components from acidic and basic drugs by extracting a basic aqueous solution with an organic solvent, and then washing this solvent with aqueous acid. Only the neutral materials should remain in the organic solvent.

Other procedures such as extraction and derivatization may be required for drugs derived from plant materials. Special precautions may be necessary when the drugs in these materials are not stable under certain conditions – in the presence of acid or base for example. However, because of the complexity of the extracts from most plants, NMR is usually not the method of choice for analyzing these materials.

For drugs where only one optical isomer is allowed in the product, or where there is a limit set on the isomeric content, procedures involving the addition of chiral shift reagents, chiral solvating agents (CSAs), or reaction with chiral derivatizing agents (CDAs) are required (see section 2.3.1.4).

In cases where the study will include the modern “hyphenated techniques” (NMR/HPLC, NMR/MS, HPLC/NMR/MS, etc.) the sample preparation may have to be changed to accommodate these other methodologies (see section 2.3.3).

When the pharmaceutical product under study is a protein or polypeptide, considerable effort may be necessary to find optimal conditions (pH, temperature, buffer strength, etc.) at which the sample is soluble, stable and nonaggregating at relatively high concentrations (usually >1 mM).

2.3 Nuclear Magnetic Resonance Experiments

Since the mid-1980s, NMR techniques have advanced dramatically. As the number of experiments increases, many spectroscopists find it difficult to keep up with all the newest procedures available to help solve problems. Most develop a set of experimental techniques which work well for them in obtaining the kind of information they require. What follows is a discussion of the general types of experiments which are most often used in the analyses of pharmaceuticals.

2.3.1 One-dimensional Techniques

2.3.1.1 High-resolution Spectra

When most scientists with a passing knowledge of NMR think about this technique, they recall the traditional 1-D high-resolution proton (1H) and carbon (13C) spectra. These spectra are highly informative in the hands of a trained NMR spectroscopist. For those who may not be experts in the field, these spectra may still be used as “fingerprints” for comparison with spectra of authentic materials. For this type of work, the use of 13C-NMR spectra is most suitable. 1H-NMR spectra are not as convenient for a number of reasons, the main one being that the appearance of the proton spectra differs significantly when obtained at different field strengths – the higher the field, the more first-order (and thus simpler) the spectra become. At lower field strengths, the 1H-NMR spectra for many drugs consist of broad and uninterpretable envelopes of signals, whereas at higher fields the corresponding spectra contain large numbers of sharp resonances which may be readily assigned using some of the modern techniques discussed below. This may be clearly seen by comparing the 80 MHz and 400 MHz spectra of phencyclidine hydrochloride (Figure 1). On the other hand, 13C spectra look very similar, regardless of the field strength used. The only differences would be for those signals which may only be resolved from each other at higher field strengths.

1H-NMR spectra can give detailed information on the nature of unknown substances. Each different proton in the molecule gives rise to a peak or group of peaks. When there is no overlap in the 1H-NMR spectrum, integration may be used to obtain the relative number of each type of proton. The chemical shift of the protons indicates the environment in which they exist. The majority of protons fall in a range of about
10 ppm. The chemical shifts in organic solvents are usually referenced to tetramethylsilane (TMS), which is assigned a value of 0.00 ppm. In aqueous solutions, chemical shifts may be referenced to 2,2-dimethyl-2-silapentane-5-sulfonate (DSS), also at 0.00 ppm. Chemical shifts provide evidence as to whether the protons are aliphatic (0.8–3.0 ppm), olefinic (4.5–6.5 ppm), or aromatic (6.5–8.5 ppm). Protons attached to carbons that are bonded to nitrogen resonate at about 2.0–3.5 ppm, while if the carbon is bound to an oxygen, the protons resonate at about 3.3–4.5 ppm. Aldehyde protons are found around 8.5–10.0 ppm. Complete tables of chemical shifts may be found in most introductory NMR text books. These would include older books such as those by Bible,\(^1\) Abraham,\(^2\) and Emsley et al.,\(^3\) as well as some more recent ones such as that by Günther.\(^4\) A collection of \(^1\)H-NMR spectra for a large number of compounds may be found in the Aldrich Library.\(^5\) Examination of the proton spectrum of the drug ketoconazole (Figure 2), shows resonances for many types of protons in the chemical shift ranges indicated.

High-resolution \(^1\)C-NMR spectra also provide a great deal of information. The chemical shift range for carbon is more than 200 ppm. As with protons, the chemical shift ranges are indicative of the kind of carbon. Carbon chemical shifts follow basically the same order as protons, with aliphatic carbons being at highest fields, followed by olefinic and then aromatic carbons. Acid and ester carbonyls are at lower fields than aromatic carbons, followed by aldehydes and isolated (nonconjugated) carbonyls at lowest fields. As with protons, tables of typical chemical shifts may be found in most introductory NMR text books which discuss \(^1\)C-NMR. These would include older books such as those by Stothers,\(^6\) Wehrli and Wirthlin\(^7\) and Levy and Nelson\(^8\) as well as the newer books mentioned previously.\(^4,5\) Figure 3(a) shows the \(^1\)C-NMR spectrum of ketoconazole, with resonances in the ranges indicated.

The number of carbon signals (excluding those from the solvent) usually gives a direct count of the number of chemically distinct carbons in the molecule being studied. Exceptions occur when two or more different carbons have chemical shifts that are too close to be resolved under the conditions of the experiment, when one or more carbons are coupled to another magnetic nucleus that is not decoupled (\(^{19}\)F or \(^{31}\)P, for example), or in special circumstances when equilibria between two or more forms of the drug exist in solution (due to hindered rotation, ring inversion, keto-enol equilibria, etc.). In a routine \(^1\)C-NMR spectrum, the signals obtained for
Figure 3 $^{13}$C-NMR spectra for ketoconazole: (a) normal carbon spectrum (large peaks at 77 ppm are due to the solvent CDCl$_3$); (b) distortionless enhancement by polarization transfer (DEPT) spectrum (CH and CH$_3$ resonances give positive peaks, CH$_2$ gives negative peaks, quaternary carbons – including the CDCl$_3$ solvent – do not give any peaks).

quaternary carbons are smaller than those for protonated carbons. It is possible to obtain carbon spectra such that each carbon gives rise to the same size peak by using long relaxation times between scans and taking precautions to eliminate the nuclear Overhauser effect (NOE) (see section 2.3.1.2). When this type of quantitative experiment is performed, one can easily determine if there are unresolved carbon shifts or if any carbons are coupled to any other nuclei, thus enabling the analyst to get an accurate count of the number of carbons in the molecule.

One very important class of 1-D experiment is that which gives a count of the number of protons attached to each carbon. Perhaps the best known of these is DEPT. With a suitable choice of experimental parameters, the $^{13}$C spectra obtained will have positive peaks for CH and CH$_3$ groups, negative peaks for CH$_2$ groups and no signal for quaternary carbons. Varying the parameters allows one to obtain spectra with only CH or CH$_2$ or CH$_3$ carbons appearing. Thus one can readily determine the number of protons attached to every carbon in the compound being studied. The DEPT spectrum for ketoconazole is shown in Figure 3(b). Comparison with the regular carbon spectrum (Figure 3a) illustrates how easy it often is to determine the number of protons attached to each carbon.

Although it is more common to obtain high-resolution spectra for protons and carbons, spectra may be obtained for many other nuclei. Those which are most often studied include $^{15}$N, $^{19}$F and $^{31}$P. Many drugs contain nitrogen, but the low natural abundance and relative insensitivity of the $^{15}$N nucleus make it a very difficult atom to study without isotopic labeling. Comparatively large amounts of material are required in order to obtain spectra in a reasonable period of time. Despite this, a number of reports have been published containing $^{15}$N chemical shift data for pharmaceuticals. The other two nuclei ($^{19}$F and $^{31}$P) are essentially 100% abundant and are NMR sensitive, but unfortunately they occur in relatively few drugs.

2.3.1.2 Nuclear Overhauser Effect When magnetic nuclei are spatially close to each other, there is a dipolar interaction. If the chemical shift of one of these nuclei is irradiated in order to saturate its spin, any nuclei that are close to it may experience a small change in the size of their signal, referred to as the NOE. For small molecules, such as traditional pharmaceuticals, this effect is usually a signal enhancement. (For larger proteins, the effect may be close to zero or even negative.) The closer the nuclei are to each other, the greater the effect on the signal. The maximum amount of enhancement for small molecules is only a few percent of original size of the signal. Because the strength of the dipolar interaction falls off at a rate which is proportional to
the inverse of the distance raised to the sixth power, nuclei must normally be within about 5 Å of each other to see any observable enhancement. To observe the small signal enhancements, one must obtain a difference spectrum by subtracting a reference spectrum obtained under “identical” conditions. (The only difference is that the reference spectrum is obtained while irradiating at a blank part of the spectrum instead of at the chemical shift frequency for one of the nuclei.) When the difference spectrum is plotted, one obtains a large negative peak for the irradiated nucleus and small positive peaks for nuclei experiencing an observable NOE. Thus this procedure often indicates which protons are close to each other in space, thus allowing the spectroscopist to determine the relative stereochemistry in unknown molecules.

2.3.1.3 Lanthanide Shift Reagent Studies The magnetic moments of the unpaired electrons of paramagnetic reagents are capable of producing relatively large chemical shift changes in molecules which are in close proximity. Most paramagnetic reagents are detrimental to the appearance of NMR spectra because they cause severe line-broadening of all the signals. However, a few complexes of the rare earth elements (lanthanides) do cause substantial chemical shift changes without substantial line-broadening on lower-field-strength instruments. The most common of these, referred to as lanthanide shift reagents (LSRs), are composed of complexes of europium, praeodymium or ytterbium with a number of different diketones. The most popular LSRs are complexes with 6,6,7,8,8,8-heptafluoro-2,2-dimethyloctane-3,5-dione [Eu(fod)3, Pr(fod)3 and Yt(fod)3]. These materials work in basically the same manner as LSRs, but when these compounds are used they may induce different chemical shift changes for nuclei of optical antipodes. The LSRs have been used to obtain optical isomer contents for many drugs.

When a shift reagent is added to a solution of the pharmaceutical, it forms a weak bond to the most basic site in the drug – usually a nitrogen or oxygen. The amount of change in the chemical shift is inversely proportional to the distance between the lanthanide atom and the proton (or carbon). The experimental procedure followed in this type of study is to obtain a spectrum of the drug alone and in the presence of varying amounts of the shift reagent. By following the shifting of the different nuclei, one can determine their relative distances from the reagent, thus providing help in assigning the shifts to the appropriate nuclei. In the case of proton studies, the spreading out of the resonance signals may cause the spectrum to be more first-order and thus easier to interpret.

The amount of line-broadening experienced by nuclei with a given concentration of LSR is directly proportional to the square of the magnetic field strength. Thus, these reagents are not suitable for use on the more modern high-field spectrometers. However, on lower-field instruments they have been used for a wide variety of drugs over the years.

2.3.1.4 Optical Purity Methods Another important class of 1-D experiments is that used to determine the optical isomer content of drugs. For a number of drugs only one isomer should be present in the commercial product. There are three basic types of NMR experiments which may be used to determine the optical purity of pharmaceuticals. The first method to be developed was the use of chiral lanthanide shift reagents (CLSRs). A related method developed later was the use of chiral solvents or CSAs. The final method is the use of CDAs.

The use of LSRs was discussed in section 2.3.1.3. A number of shift reagents have optically active ketone groups. Some of the common CLSRs include complexes with the ligands 3-(trifluoroacetyl) -d-camphor [Eu(tfc)3], 3-(heptafluorobutyryl)-d-camphor [Eu(hfc)3] and d,d-dicampholylmethane [Eu(dcm)3]. These materials work in basically the same manner as LSRs, but when these compounds are used they may induce different chemical shift changes for nuclei of optical antipodes. The CLSRs have been used to obtain optical isomer contents for many drugs.

An alternative to CLSRs is the use of one of a series of compounds referred to as chiral solvents or CSAs. These are optically active compounds possessing an aromatic group and a polar functional group such as an amine, alcohol or acid. When a suitable CSA is added to a solution of a drug which also has a polar group, the CSA forms a weak hydrogen bond with the drug. Because the CSA is optically pure, it forms different complexes with each optical antipode of the drug. The aromatic ring current of the CSA is located at different distances from the corresponding nuclei in the drug isomers. This causes the nuclei of the drug to give rise to separate signals for each antipode, thus enabling the optical purity of the drug to be determined. Unlike the CLSRs, no line-broadening occurs when CSAs are used. Higher-field spectrometers provide better separation of signals than lower-field instruments. The structures of some of the more common CSAs are shown below (1–8).

A third method for determining the optical isomer content of drugs is the use of CDAs. As with CSAs, the CDAs usually contain an optical center and an aromatic group. They also contain a functional group (such as an acid chloride) which is capable of reacting and forming a covalent bond with the drug. As with the CSAs, the aromatic group is in different proximity to the nuclei of the drug’s antipodes, causing differential shifts in some of the corresponding resonances. In many cases, this difference is sufficient to allow accurate quantification of each isomer. Once again, there is no line-broadening as with CLSRs and the higher-field
NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY IN PHARMACEUTICAL ANALYSIS

2.3.2 Two-dimensional Techniques

2-D techniques in NMR spectroscopy all involve multiple-pulse experiments containing three basic stages – preparation, evolution and detection. The spectrum that is finally obtained depends on the nature of the preparation and the length of the evolution time. The effects of evolution are not observed directly, but are detected by carrying out a series of experiments in which the evolution time is systematically varied. By following this procedure, two distinct sets of spectroscopic features are obtained – those that influence the magnetization during the evolution time and those that influence the magnetization during the acquisition time. In 1-D NMR Fourier transformation is used to convert the time dependence of the magnetization evolution during the acquisition time into frequency data, while 2-D NMR uses a second Fourier transformation to convert the time dependence of the evolution time into a second frequency.

2.3.2.1 $^1H-^1H$ Correlation Spectroscopy Experiments

One class of 2-D experiments, which may be performed on any modern high-resolution NMR spectrometer, is referred to as correlation spectroscopy (COSY). One of the most common 2-D experiments is $^1H-^1H$-COSY. The results for this type of experiment are usually displayed as a 2-D contour plot with the 1-D proton spectrum plotted along both the $x$- and $y$-axes. A typical COSY spectrum is shown in Figure 4 for the drug ketoconazole. The contours in this plot indicate the chemical shifts of the protons that are coupled to each other. Thus, to determine which protons are coupled to a particular proton resonance, one simply scans down a column beneath the peak plotted on the $x$-axis. Contours will be found on rows corresponding to peaks plotted on the $y$-axis for protons to which there is detectable coupling. By varying the experimental parameters, one can look for either larger short-range or smaller long-range coupling constants. This experiment allows the spectroscopist to determine which protons are separated from each other by two, three or even four bonds.

2.3.2.2 $^{13}C-^{13}C$ Correlation Spectroscopy Experiments

The other homonuclear shift correlation experiment which may be used by spectroscopists is $^{13}C-^{13}C$-COSY. This technique is often referred to in the literature by the acronym INADEQUATE (incredible natural abundance double quantum transfer experiment). This is a very powerful technique which shows all the

Figure 4 $^1H-^1H$-COSY spectrum of ketoconazole. Contours can be used to determine which protons are coupled to each other by examining the proton spectra plotted along the top and side.
one-bond carbon–carbon connections in the molecule, enabling the complete skeleton of the compound to be determined, except for those parts joined by heteroatoms. However, because of the extremely low sensitivity of this experiment, and the length of time required to accumulate the data, it is seldom used. Instead, spectroscopists use a combination of other techniques to get the same information much more quickly.

2.3.2.3 $^{13}$C–$^1$H Correlation Spectroscopy Experiments
Because of the importance of determining the connections between hydrogens and carbons, a large number of $^{13}$C–$^1$H-COSY experimental techniques have been developed. In the 2-D contour plots for this type of experiment, the carbon spectrum appears along one axis and the proton spectrum along the other. Parameters may be chosen to emphasize large coupling constants to observe one-bond couplings, or to emphasize smaller couplings so that two- and three-bond couplings may be observed as well. A $^{13}$C–$^1$H-COSY spectrum showing one-bond couplings for ketoconazole is presented in Figure 5. In a related experiment, called relayed coherence transfer (RCT), parameters are used which give contours for each carbon atom corresponding to the directly attached protons as well as all the protons coupled to them (i.e., protons on nearby carbons).

2.3.2.4 Nuclear Overhauser Effect Spectroscopy
In section 2.3.1.2 the 1-D NOE experiment was discussed. There is a corresponding 2-D version of this experiment which goes by the acronym NOESY (nuclear Overhauser effect spectroscopy). Although the $^1$H–$^1$H version of this experiment is more popular with the pharmaceutical analyst, the $^{13}$C–$^1$H version is also available. In the 2-D plot, contours are found for each pair of nuclei which would have produced a medium to strong NOE in the 1-D counterpart. In the 2-D experiment, some weak interactions that are detectable in the 1-D method are sometimes missed. However, in a single 2-D experiment one can get most of the results that would be obtained in many 1-D NOE experiments.

During recent years, advances in NMR technology have led to techniques which provide increased sensitivity over these 2-D methods just discussed. These advances include the introduction of "inverse" or "reverse" detection probes, gradient probes, and decouplers which are capable of producing shaped pulses. These exciting advances mean that the pharmaceutical analyst can determine the structures of unknown samples with ever decreasing amounts of material.

2.3.2.5 Protein Techniques
The proton spectra of individual amino acids are relatively easy to obtain and interpret. However, in proteins the large number of signals creates extensive overlap, making it impossible to interpret the normal 1-D spectrum. For larger proteins, even the 2-D experiments discussed previously are often not sufficient to allow chemical shift and structural assignments. Use of higher order (three-dimensional (3-D) and four-dimensional (4-D)) experiments has allowed the spreading of signals into more dimensions, making them more tractable. To perform many of these multidimensional experiments, it is necessary to have protein that is enriched (i.e. isotopically labeled) with $^{12}$C and $^{15}$N (and sometimes $^2$H).

There are several problems involved in performing higher dimensional experiments. Each increase in dimension greatly increases the experimental time required to obtain the data. The multidimensional experiments require much higher concentrations of protein to reduce the amount of signal averaging for each acquisition. The 3-D and 4-D experiments require more complex spectrometer hardware and probes than the 1-D and 2-D techniques. The resulting data in the higher dimensional experiments also have reduced digital resolutions in some dimensions.

One class of 3-D experiments involves combining two 2-D $^1$H experiments. This serves to reduce the overlap of signals by spreading them into the third dimension. The advantage of this type of experiment is that it does not require any isotopic labeling. A second class of 3-D experiments combines a 2-D $^1$H experiment with a 2-D $^1$H–X nucleus experiment (where X is usually $^{13}$C or $^{15}$N). This type of experiment takes advantage of the
wider shift range of the $X$ nucleus and also allows the chemical shifts for the $X$ nuclei to be assigned. This class of experiment requires that the protein be labeled with the $X$ nucleus. Usually, data from several of these experiments are required to make full assignments for larger proteins. A third class of experiments is used to trace connectivities along the protein peptide backbone or along the side-chains. These experiments, which correlate three different nuclei ($^1H$, $^{13}C$ and $^{15}N$), require doubly labeled protein. The NMR probes must have at least three frequency channels and the spectrometer must have as many as five transmitters. These experiments allow determination of correlations between sequential residues. For example, some experiments allow the correlation of the amide proton on one residue with the $\alpha$-carbon of the preceding residue. Additional new experiments and refinements of older experiments have appeared over the last several years, and no doubt will continue to do so.

2.3.3 Hyphenated Techniques

One of the drawbacks of NMR spectroscopy has traditionally been its inability to easily positively identify small amounts of compounds in the presence of large amounts of other material. If the compound had resonances that were not overlapped with those of the main material, one could get some evidence of its presence and of its level, but because most of its resonances could not be observed, the identification usually had to be confirmed by another method. With techniques such as MS, gas chromatography (GC) or HPLC is used to separate each component before analysis. Over the last several years considerable work has been done on coupling NMR with HPLC in an analogous manner (see Keifer$^9$ and references therein).

A number of problems had to be solved in order to make HPLC/NMR a feasible technique for pharmaceutical research. One of the main concerns was with the sensitivity of NMR spectrometers. Since only small amounts of sample are injected onto analytical columns, older NMR instruments could not be used to detect the components coming off the column. Also, the mobile phase used on the HPLC systems gave rise to large peaks in the NMR spectrum, making it very difficult to observe the resonances for the drug-related material of interest. These problems have largely been addressed and HPLC/NMR spectroscopy is now a more routine, commercially available technique that is being used in many pharmaceutical laboratories around the world. There have recently been reports of combining this technique with MS (HPLC/NMR/MS) to produce a technique which is extremely powerful for pharmaceutical analysis.

Over the last few years there have been many reports of using NMR spectrometers as the detectors for a variety of other separation techniques. These include capillary HPLC, capillary electrophoresis (CE), capillary zone electrophoresis (CZE), and capillary electrochromatography (CEC). Although not yet commercially available, these techniques may soon provide pharmaceutical researchers with very powerful structural elucidation methods in their studies of drug-related materials.

3 APPLICATIONS

3.1 Confirmation of Known Compounds

While the majority of drugs may be just as easily identified by other methods, such as infrared (IR) spectroscopy and MS, NMR is used in many pharmaceutical laboratories. Some drugs that possess hygroscopic or polymorphic properties are difficult to analyze by IR spectroscopy. Also, many drugs fragment in such a manner that their mass spectra are ambiguous and difficult to interpret, especially in cases where there may be a number of closely related isomers. NMR provides an attractive alternative approach for these types of drugs since it is not affected by these kinds of problems and provides a very powerful method for distinguishing between isomeric drugs.

3.2 Identification of Unknown Compounds

NMR spectroscopy provides the analyst with one of the most powerful techniques for the identification of unknown compounds. For laboratories with modern spectrometers, the full range of experiments described in section 2.3 is available. While IR spectroscopy and MS are useful for identification of known compounds, especially by means of their library search capabilities, NMR is usually a key spectroscopic technique for identifying true unknowns.

The exact series of NMR experiments used to solve unknown structures may vary somewhat, depending on the preferences of the particular spectroscopist. However, the general procedure will be the same. The analyst will carry out the following series of experiments until enough information has been obtained to identify the unknown, or until enough information is obtained so that the investigator will be able to determine which specialized experiment is required to complete the study.

First, the drug-related sample is prepared for study as described in section 2.2. Then the spectroscopist obtains a high-resolution $^1H$-NMR spectrum using an appropriate deuterated NMR solvent. Careful inspection of this spectrum gives a great deal of structural information. Chemical shifts and integration reveal the relative number of protons in each area (aliphatic, olefinic, aromatic) and the coupling patterns may reveal information on the proximity of many protons. Next, $^{13}C$-NMR and
DEPT spectra are obtained to determine the number of different carbons and the numbers of protons attached to each. Chemical shifts of the carbons give important information about each carbon’s environment. Often, the combination of proton and carbon data is enough to solve the structure of the unknown. If it is not, 2-D spectra and NOE experiments are used to establish connectivity and proximity of the nuclei in the molecule. The information obtained is often sufficient to establish the skeleton of the molecule. Sometimes, especially when there are NMR “silent” nuclei (such as chlorine, bromine, oxygen, nitrogen, etc.) present, it may be necessary to obtain MS and/or IR data in order to complete the structure. While it is true that spectra can be obtained for most of the “silent” nuclei, it is usually much quicker and easier to use these other spectroscopic techniques to establish their presence.

In studies to determine the identity of unknown compounds, it is often helpful to compare the NMR chemical shifts with those of related known substances. For example, if one were trying to identify drug metabolites or impurities, one could compare the spectra with those of the drug itself. If the chemical shift assignments are not already known, one can use the above sequence of experiments to establish them. Then, by determining which resonances are present in both and which have changed or disappeared, one can determine which part of the drug has changed. This is of particular advantage in cases where one has a relatively large amount of the drug and the amount of unknown available is small, thus limiting the types of experiments which may be performed on the unknown.

### 3.3 Quantification

When quantification is required, sample preparation procedures are more demanding than those for routine samples (discussed in section 2.2). If absolute quantification is required, the amount of sample used must be accurately known and an accurately known amount of a suitable standard must be added to the sample before the analysis. If only relative quantities of substances present are required, there is no need for an internal standard. If an extraction procedure is necessary, one must be sure that the drug-related material is quantitatively removed.

An appropriate internal standard must be chosen to ensure accurate quantification. This standard must meet a number of strict criteria. It must be pure (or at least be of known purity) and be soluble and stable in the solvent used for analysis. It must not react with any compounds present (including the solvent). For convenience, it is usually easier to work with a solid standard, but if a liquid is chosen, it should be nonvolatile in order to avoid losses during the sample preparation and analysis. Lastly, the standard must have an appropriate NMR spectrum such that both the drug-related material and standard have well separated resonances whose integrals or peak heights may be used in the quantification. It is usually best to choose a standard which has either a suitable singlet or narrow multiplet to minimize the chances of overlap of signal resonances.

The choice of nuclei for NMR quantification is important. For relatively simple mixtures, $^1$H-NMR, because of the shorter relaxation times and higher sensitivity when compared with $^{13}$C-NMR, is often the method of choice. However, for more complex mixtures, $^{13}$C-NMR may prove to be the better option. Although NMR is well suited for quantification of drugs, relatively few publications have appeared in this area. In part this is due to the fact that this method is considered to be so routine as to not warrant publishing these kinds of results. More recently, however, a number of publications have appeared (e.g. Lacroix et al.\(^{10,11}\)) which show that NMR gives analytical results comparable to those obtained by other methods, such as HPLC (see sections 3.4 and 3.5). These papers point out the advantages of NMR over these alternative methods, indicating that NMR should be used more routinely for quantification purposes.

There are basically two approaches to obtaining the accurate quantification of drugs or impurities by NMR techniques. In the first, one must wait a relatively long time ($>5T_1$ for the longest relaxation time) to ensure equal responses for each of the nuclei being studied. The second method requires that spectra be acquired and processed under identical conditions and that a calibration curve, with appropriate amounts of the standard and analyte covering the range of interest, be obtained. The first method has the advantage of not requiring pure compounds (used to create the calibration curve in the second) because the relative response of the nuclei is known. Its main disadvantage is the amount of time required to acquire the spectra due to the long relaxation delay between pulses. Another disadvantage appears in the processing of the data. Because of differences in peak widths, areas from integrations must be used and care must be taken to avoid problems due to baseline distortions which may adversely affect the analyses. The second method has the advantage of shorter acquisition times for the spectra, but requires that appropriate standards be available and calibration curves be obtained. Another advantage of the second method is that because a calibration curve is being used, it is possible to use peak heights instead of areas (although areas may still be used). Using peak heights with calibration curves has allowed the simultaneous quantification of a relatively large number of impurities in the drug fenofibrate\(^{10}\) at relatively low levels ($<0.1\%$). This is considerably better than results reported for other drugs using integration, where the lower limits are reported to be about $1\%$. 

\(^{10}\) PHARMACEUTICALS AND DRUGS
3.4 Impurity Profiling

When a ¹H-NMR spectrum is taken for a drug, signals are obtained for the protons of the impurities as well as for the pharmaceutical itself. Careful examination of these “extra” peaks will often allow the identification of one or more impurities. Integration, or comparison of relative peak heights, will usually give a very good estimate of the percentage of each impurity present. As long as there are unique resonance peaks for each impurity, large numbers of impurities may be quantified from a single spectrum. This was amply illustrated by Lacroix et al. for the drug fenofibrate. In this study, 12 known impurities, as well as a number of unknowns, were quantified at levels of <0.1% in drug raw materials from several manufacturers.

In cases where the impurity(ies) cannot be identified in the presence of the drug, it is often possible to separate it (them) from the drug using the extraction methods discussed in section 2.2. Once the drug resonances no longer mask the impurity peaks, it is much easier to perform the required NMR techniques to identify the material. Alternatively, if an HPLC method exists for separating the impurity, the eluted peak may be collected and analyzed by NMR. If the HPLC and NMR are interfaced, the impurity may be studied without having to go through the collection step.

3.5 Optical Purity

For a number of drugs only certain optical isomers are supposed to be present in the commercial product. Using the methods described in section 2.3.1.4, NMR methods for determining the optical purity for many of these drugs have been reported. Most of the earlier studies were done on lower-field-strength instruments, using CLSRs. The limit of quantification for these studies was typically 1–5%. The later studies, using higher-field-strength instruments and CSAs or CDAs provide much greater sensitivity, with detection limits in some cases of much lower than 0.1%. For example, Lacroix et al. used (R)-(−)-2,2,2-trifluoro-1-(9-anthryl)ethanol with drug raw material for timolol maleate, enabling them to easily detect the optical impurity at levels of 0.1% at a relatively low field strength (400 MHz). These kinds of results make NMR a very attractive method for determining if pharmaceutical products meet the requirements set by pharmacopoeias of many countries.

3.6 Analysis of Body Fluids

In many cases analysts studying drug metabolism will analyze samples of body fluids in attempts to measure levels of the drugs and/or their metabolites. The concentration of drugs in the blood varies over a wide range – from tens of milligrams per milliliter for ethanol to nanograms per milliliter for most drugs and their metabolites. However, in some extreme cases of overdoses, drug levels of 100 mg mL⁻¹ are observed. The lower ranges of these drug and metabolite levels are beyond the sensitivity of NMR, but the higher end values are not. Detection limits for ¹H-NMR are below the microgram per milliliter range on newer high-field spectrometers using the hyphenated techniques discussed in section 2.3.3. Without these methods, it has proved difficult to obtain these lower limits due to the background signals from endogenous compounds in the blood and urine samples. The fluorine signals of fluorinated steroids are detectable at submicrogram-per-milliliter levels because there is no background. For nonfluorinated drugs, analysts who do not have access to the hyphenated techniques have the option of performing sample work-up procedures such as solid-phase extraction (SPE) or preparative HPLC clean-up before analysis. This also allows the analyst the opportunity to concentrate the drug or metabolite from several milliliters down to the volume (<0.5 mL) required for NMR analysis, thus bringing many more samples into the range of levels detectable by NMR.

4 COMPARISON WITH OTHER TECHNIQUES

4.1 Advantages

NMR will detect all organic compounds present in the sample. Other techniques, such as HPLC or MS, will often not detect impurities. For example, these techniques will not observe any compounds that either elute in the solvent front or do not come off the column at all under the conditions used. Careful examination of the impurity peaks in the NMR spectrum will often give significant clues as to their identity and allow quantitative estimates as to the amounts present. HPLC provides little information about the identity of unknown impurities and is not reliable for quantifying them since it does not give equimolar responses for different materials. In fact, compounds with low or no ultraviolet (UV) absorbance may not be detected, even when present at significant levels.

NMR is a nondestructive technique. As long as the sample material is stable in the solvent chosen for the study, the entire sample may be recovered and then used for other studies. Thus, since sample is used up in other techniques such as HPLC and MS, the NMR studies should be performed first whenever there is a limited amount of sample.

NMR spectroscopy provides the most powerful structure elucidation technique available to the pharmaceutical analyst for unknown materials. One area where...
NMR outshines other spectroscopic techniques is in the determination of isomers. Its true value comes from its ability to establish the proximity of nuclei in a molecule using coupling constants (through one, two or three bonds) or with NOE measurements (for nuclei within approximately 5 Å). The NMR chemical shifts and coupling constants easily allow the discrimination of geometric or positional isomers, even when there are no authentic materials for comparison purposes. It would be much more difficult, if not impossible, to get this same information using other spectroscopic techniques such as IR spectroscopy or MS (without reference standards).

The most common method for an analyst to determine the optical purity of drugs has been by either specific optical rotation or HPLC, using a chiral column or a chiral derivatization procedure. However, NMR has a number of advantages over optical rotation and HPLC in studies aimed at determining the enantiomeric composition of any organic compounds, including pharmaceuticals. This is especially true if methods are required that are capable of analyzing for optical antipodes at levels of less than a few percent. This may be important if one wishes to confirm that a pharmaceutical meets the requirements of a country’s pharmacopoeia. Using modern spectrometers and the techniques described previously, it is usually possible to develop methods that can quantify the drug’s enantiomer at or below levels of 0.1%. Some of the advantages of NMR are given here.

1. NMR results are accurate and precise, even at low percentages. Optical rotation cannot be used to determine low levels of impurity, especially in drugs with a low specific optical rotation.

2. The time required for analysis is usually less for NMR than for HPLC. This is especially true if there is no existing method, since it is usually quicker to develop an NMR method than an HPLC method. If a method already exists, it is still much faster to get the results by NMR. For NMR, the procedure would normally involve simply dissolving the drug in an appropriate solvent, adding the calculated amount of CSA, acquiring the proton spectrum and measuring the proper peaks in the spectrum. This may normally be done within half an hour. For HPLC, one must set up the liquid chromatography system (put in the proper column, prepare the mobile phase, etc.), check the performance of the column by running a standard and then run the sample. All this requires much more than half an hour.

3. NMR methods are more “robust” than HPLC methods. Once a method has been developed for NMR, it should work on any spectrometer of equal field strength (or higher field strength for CSAs and CDAs). Because of the variability of columns, HPLC methods have to be checked and sometimes modified when changing columns.

4. NMR provides “bonus” information. Since NMR detects all signals for the nucleus under study, it will detect not only the drug (and its enantiomer), but also any impurities present.

4.2 Disadvantages

One of the main criticisms of NMR as an analytical technique is its relative insensitivity when compared with other methods such as MS or HPLC. While these other instruments may require only nanograms or less of the sample, NMR usually needs micrograms or more. While this limitation is of little concern for drug raw materials or dosage forms, it does limit its use in analyses of body fluids for drugs and their metabolites.

Another common complaint about NMR is the cost of the instrumentation. While it is true that highest-field-strength spectrometers are very expensive (millions of dollars each), the models that have been around for several years (currently field strengths of 200–600 MHz) tend to be comparable in cost to mass spectrometers. In general, NMR spectrometers have proven to be very reliable instruments, with relatively low repair and maintenance costs. Thus, if one considers the cost per year, NMR spectrometers may not be as expensive as is generally thought.

Another concern often brought up when discussing the use of NMR is the need for highly specialized expertise in the area. While it is true that considerable expertise is required in order to take advantage of the full capabilities of modern spectrometers, very little knowledge is needed to use NMR results for more routine purposes. Thus, for positive identification of known compounds, simple comparisons of spectra with those of authentic materials is all that is required. This is very similar to the use of IR spectroscopy “fingerprinting” to identify compounds. It is also possible to automate the identification by use of library searches of NMR databases, comparable to those for IR spectroscopy or MS.

5 CONCLUSIONS

NMR has played a key role in pharmaceutical analysis in the past and promises to play an even more crucial role in the future. The ever increasing sensitivity and capabilities of the most modern spectrometers provide pharmaceutical analysts and researchers with more powerful tools to tackle their analytical problems. There is no doubt of the vital role to be played by NMR in studies
NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY IN PHARMACEUTICAL ANALYSIS

of the newer biotech pharmaceuticals in the areas of structure and drug interactions. In studies of traditional synthetic drugs, NMR, especially in conjunction with other analytical techniques such as MS and HPLC, will continue to have a critical function.

Planar Chromatography in Pharmaceutical Analysis

A.P. Argekar
The Institute of Science, Mumbai, India

1 INTRODUCTION

Planar chromatography is a liquid chromatographic technique in which the stationary phase is arranged in the form of a planar or flat bed and the mobile phase moves by capillary action. Thin-layer chromatography (TLC) is the most widely used planar chromatography. Modern TLC is an instrumental version of conventional TLC known as high-performance thin-layer chromatography (HPTLC). Rotation planar chromatography (RPL), high-speed thin-layer chromatography (HSTLC), and over-pressed liquid chromatography (OPLC) are some other forms of planar chromatographic methods.

The application of HPTLC techniques for pharmaceutical analysis, such as the determination of active pharmaceutical ingredients (API) and the content uniformity test (CUT) of dosages, purity and stability tests of drugs and drug products, process monitoring of formulations, and herbal drug analysis, is described in this article. The method development of the high-performance liquid chromatography (HPLC) technique, various pharmaceutical regulations and methods, validation and quality assurance (QA) of HPTLC experimental data and documentation are also described. The comparison of HPTLC with other chromatographic techniques is also discussed.
as bulk drug substances and pharmaceutical products (formulations). This article is concerned mainly with planar chromatography together with capillary flow, namely HPTLC for pharmaceutical analysis.

2 HISTORY

The history of TLC has been reviewed by several authors. Ismailov and Shraiber separated certain medicinal compounds on an alumina spread on a glass plate, in 1938. Meinhard and Holl in 1949 used a binder to adhere alumina to microscope slides to separate certain inorganic ions. In the early 1950s, Kirchner and colleagues used sorbents held on glass plates with the aid of a binder, and the plates were developed with the conventional ascending procedure used in paper chromatography. Stahl introduced the term “TLC” in the late 1950s. Quantitative TLC was introduced in 1954 by Kirchner et al. Densitometry in TLC was initially reported in the mid-1960s by Dallas et al., Genest, and Thomas et al. HPTLC plates having fine particle layers were produced commercially in the mid-1970s, and in the late 1970s forced-flow planar chromatography was introduced.

TLC will continue to grow as a highly selective, sensitive, quantitative, rapid, and automated technique for the analysis of all types of samples and analytes, and for preparative separations.

3 SAMPLE PREPARATION

Sample preparation for TLC is not as demanding as for other chromatographic techniques as the plates are disposable products. However, several steps for sample pretreatment may be necessary, which include mechanical crushing, extraction steps, filtration and sometimes enrichment of interesting desired components, or removal of undesirable impurities. Proper sample preparation is an important prerequisite for the success of TLC separation. The sample preparation procedure is to dissolve the drug with complete recovery of intact compounds of interest and minimum of matrix with a suitable concentration of analytes for direct application on the TLC or HPTLC plate. Besides maximizing the yield of analytes in the selected solvent, the stability of analytes during extraction and analysis must be ensured. Therefore, the choice of a suitable solvent is very important. For normal-phase chromatography using silica gel-precoated plates, the solvent for dissolving the sample should be nonpolar and volatile as far as possible. This is because polar solvents are likely to induce circular chromatography when the sample is employed incrementally, leading to spreading of the spot and thus loss of separation efficiency. For reversed-phase chromatography polar solvents are usually used for dissolving the sample; however, such polar solvents must wet the layer so that the sample penetrates the layer uniformly. It is preferable to use the minimum possible amount of solvent, the quantity employed being limited to ensure complete extraction of analytes but the minimum of extraneous components. Sample and reference substances should be dissolved in the same solvent to ensure comparable distribution at the starting zone. Most sample preparation procedures require concentration or evaporation of the sample extracts. It is important that evaporations are carried out without loss or degradation of the analyte. Common methods for concentration are rotary evaporation and nitrogen blow down. Common practice is to evaporate solutions just to dryness and then to dissolve the residue in an exact volume of the same or different solvent from which a known aliquot or the total sample is applied to chromatoplates.

4 PHARMACEUTICAL APPLICATIONS

There is a comprehensive literature dealing with TLC systems for pharmaceutical analysis. Manufacturers of HPTLC instrumentation provide instrument validation and support for all users performing analysis in the fields of herbal, bulk drugs, and pharmaceutical formulations. Pharmaceutical applications of HPTLC analysis are summarized in Table 1. The only limitation of HPTLC

so far as pharmaceutical analysis is concerned is that it cannot be employed for dissolution testing studies.

### 4.1 Pharmaceutical Products

Drugs are defined as substances or products that are intended for modification or exploration of physiological states for the recipient. The drugs are prescribed in a variety of forms such as tablets, capsules, injections, ointments, intravenous fluids, syrups, etc. termed as pharmaceutical products, formulations, or dosage forms. As HPTLC requires minimal sample cleanup, interference from the excipients in tablets, the high quantity of fatty matter in creams, and the sugar base of lozenge formulations pose no problems in HPTLC analysis. Therefore, the active drug components either in single or mixed dosage forms are estimated economically and speedily. Table 2, summarizes HPTLC applications for the determination of the API from formulations.

As specified in United States Pharmacopeia XXIII, dosage forms containing 50 mg or less of active ingredient per unit must comply with a CUT. The criteria specified is that out of 10 units individually tested the contents of each unit must be within 85–115% of the labeled claim with a relative standard deviation (RSD) not greater than 6.0%. However, if one unit is outside the 85–115% range of the labeled claim and no unit is outside 75–125%, or of RSD not greater than 6.0% or both, 20 additional units must be tested. Not more than one unit out of 30 so tested is to be outside the range 85–115% and no unit is to be outside 75–125% with RSD not above 7.8%. These tests are laborious and time-consuming. However, HPTLC has been found to be the most suitable and economically viable method for testing the dosage form for compliance in respect of uniformity. Using the built-in CUT feature in CATS software, three complete CUTs can be performed in 2h. (CATS software is a Windows-based software used in quantitative TLC and is supplied by CAMAG, Switzerland.)

### 4.2 Purity Profiles

The purity of a drug and the determination of the nature and quantity of any impurities present are key questions for the modern pharmaceutical analyst. The nature and the quantity of impurities in a drug product depend upon the route of synthesis used to produce the drug substance (bulk drugs), purification procedures, manufacturing of pharmaceutical products or formulation, and the conditions under which they have been stored. Purity tests of bulk drugs are generally focused on related substances such as homologs, analogs, by-products from the synthesis or degradation, and the enantiomeric purity. HPTLC has revolutionized the ability to determine substance purity and is currently the most important check, giving essentially the fingerprint of a synthesis.

Low-level substances with relatively high retention times are poorly resolved and detected owing to peak broadening in HPLC. However, in reversed-phase high-performance thin-layer chromatography (RPHPTLC) substances with low $R_f$ (retention factor) values form strong and sharp zones, and hence have better detection sensitivity. Those substances with low retention times may appear as unresolved in HPLC, but in RPHPTLC they will usually appear between $R_f$ values of 0.5 and 0.9 and are easily detected. In RPHPTLC, the impurities can be detected either at the starting line or near the solvent front provided the plates have been properly alleviated by prewashing prior to development. Large quantities of slowly eluting substances would completely spoil the HPLC column after collection and may show memory effects, whereas slowly migrating substances in RPHPTLC will be retained near the origin.

When studying the purity profile of drugs using HPTLC, the following precautions should be considered:

- After the TLC plates have been developed, they should not be dried at an elevated temperature. This avoids any decomposition, oxidation, and hydrolysis during drying.
The solvents to be used for sample preparation or as components of mobile phase should be checked by running a blank TLC plate in the solvent. The plate should not show any spot visible under UV light or with the reagent likely to be used for the detection of impurities. This is absolutely essential because any impurity present in the solvent can give erroneous results, in that the additional spots can be mistaken to have been contributed by the substance under examination.

The application of HPTLC to the purity profile study of some drugs is illustrated by the densitograms in Figures 1–3.

Commercially available chiral HPTLC plates have made it easy to purify and quantify enantiomeric drugs. Optical purity control of L-dopa and D-pencillamine (Figures 4 and 5) are two excellent examples showing the application of HPTLC for enantiomeric drug separations.

### 4.3 Stability Studies

The purpose of stability testing is to provide evidence on how the quality of a drug substance or pharmaceutical product varies with time under the influence of a variety of environmental factors such as temperature, humidity, and light. Stability testing permits the establishment of recommended storage conditions, retest periods, and shelf lives.
Information on the stability of a drug substance or dosage form under defined storage conditions is an integral part of a systematic approach to stability evaluation. Stress testing helps to determine the intrinsic stability characteristics of a molecule by establishing degradation pathways to identify the probable degradation products and to evaluate the stability by indicating the power of the analytical procedure used.

HPTLC has been employed as a stability-indicating method for stability studies of several drugs and formulations. Three such examples are illustrated in Figures 6–8.

4.4 Process Monitoring

Profitability is directly linked to production efficiency, which in turn can be established by numerous research and development experiments. Each such experiment must be monitored closely. Based on the results of the impurity profile of the drug, the process is modified. Thus an assurance of product quality and consistency is very much in the hands of analysts. In process analysis the assay is performed either by the production department or the QC laboratory. Production departments are therefore equipped to conduct those types of in-process controls necessary to keep the process running, whereas controls that might require special equipment are conducted by the QC laboratory. The methods should be very easy to perform, fast, accurate and reproducible. They should help in the processing of drug substances during intermediate stages. Chances of contamination from previous processes is to be monitored and indicated.

HPLC and HPTLC are the two most widely used techniques in the pharmaceutical industry for process control. Process optimization needs hundreds of quick analyses, which are well executed by an HPTLC system at a low cost. Moreover one HPTLC system can support several laboratories simultaneously.

The drug norfloxacin is produced by condensing 3-chloro-4-fluoro aniline (CFA) and diethyl ethoxy methylene malonate first to yield the acrylate which, on further cyclization, yields the N-ester. On ethylation this ester gives the ethyl-N-ester which, on hydrolysis, yields acid and norfloxacin. This production of norfloxacin can be monitored by HPTLC technique, as all the compounds have absorption in the UV region at 288 nm. The densitogram of a typical production batch of norfloxacin is shown in Figure 9. The production process optimization and monitoring of oxendazole can also be performed using HPTLC (Figure 10).

4.5 Herbal Drugs

Plant substances have been used in medicines since ancient times. The composition of the drug varies widely depending on the species, geographical location, origin, climate, growth period, part of the plant, storage, and preparation procedure. Herbal formulations used in the preparation of therapeutic medicines derive their potency from constructive and symbiotic effects due to the presence of two or more crude drugs. This makes the analysis of herbal formulations more complex.
PLANAR CHROMATOGRAPHY IN PHARMACEUTICAL ANALYSIS

Figure 4 Chromatoplate showing the optical purity of L-dopa. Layer, Chiralplate™; eluent, methanol–water–acetonitrile (50 : 50 : 30 v/v/v); developing time, 45–60 min; detection, 0.1% ninhydrin reagent. 1 = L-dopa; 2 = D,L-dopa; 3 = D-dopa; 4 = 3% L-dopa in D-dopa; 5 = 3% D-dopa in L-dopa. (Reprinted by permission of K. Gunther, from Z. Anal. Chem., 322, 513–514 (1985).)

Figure 5 Chromatoplate of optical purity of D-pencillamine. Layer, Chiralplate™; eluent, methanol–water–acetonitrile (50 : 50 : 200 v/v/v); developing time, 30 min; detection, 0.1% ninhydrin spray reagent. 1 = L-5,5-dimethyl-4-thiozolidine carboxylic acid (L-3); 2 = D,L-5,5-dimethyl-4-thiozolidine carboxylic acid (D,L-3); 3 = D-5,5-dimethyl-4-thiozolidine carboxylic acid (D-3); 4 = 3% L-3 in D-3; 5 = 3% D-3 in L-3. (Reprinted by permission of K. Gunther, from Arch. Pharm. (Weinheim), 319, 461–465 (1986).)

HPTLC has been found to be the most accurate and facile technique for the analysis of herbs and their extracts over other techniques for the following reasons:

- Very little sample clean-up is needed as the layer is disposable.
- Preparative work can be very easily done.
- Fingerprinting of a large number of components of the sample matrix is possible.
- Active ingredients can be quantified.
- Short run times.
- Large numbers of analyses are possible, for reliable statistics.
- Many components in herbal medicines are fluorescent.
A large number of papers on the application of planar chromatography to the characterization of herbal medicines have been published in Chinese journals. Table 3 shows HPTLC applications for herbal formulations.

5 PHARMACEUTICAL REGULATIONS AND METHODS

There are several regulations that have to be followed in the development of pharmaceuticals as well as in their production. Regulatory approval is required prior to the investigational new drug (IND) application, before initial human testing, and also the new drug application (NDA) which summarizes the data obtained from all the studies needed for marketing approval of the drug as a medicine.

An important part of the development process is safety evaluation, primarily the toxicology tests, which run from 6 to 24 months in different species. By this time bioanalytical studies have been performed, as well as control of the formulations used in the tests. After approval for marketing the authorities exercise control of products on the market and require past production stability data. Public interest in the quality of drugs is also reflected in the compilation of substance monographs in compendia, known as pharmacopoeias, which contain

Figure 6 Densitogram of the stability profile of oxytetracycline eye drops scanned at 254 nm. Layer, silica gel TLC plates impregnated with aqueous solution of disodium ethylenediaminetetraacetic acid and activated at 130 °C; eluent, chloroform–methanol–water (65:25:5 v/v/v); saturated TLC tank. (a) On the day of the preparation, (b) On the 10th day of storage. Peaks: 1 = α-APC-OTC (α-apoxytetracycline); 2 = EOTC (4-ethoxytetracycline); 3 = OTC (oxytetracycline hydrochloride); 5 = β-APC-OTC (β-apoxytetracycline); 4,6,7 and 8 = unidentified; 9 = solvent front caused by demixing. Peaks: 1 = estradiol; 2 = estradiol benzoate; 3 = estradiol-3-benzoate-17-acetate; 4 = estradiol dibenzoate. (Reprinted by permission of publisher, Research Institute for Medicinal Plants, Hungary, from J. Planar Chromatogr., 8, 351 (1995).)
general analytical methods and also requirements on the formulation of the substances.

Good Manufacturing Practice (GMP) regulations have been a cornerstone of pharmaceutical production and control since the 1970s. These regulations state clearly what has to be done to safeguard quality from the beginning of the production process to the end, namely documentation, staff qualifications, standard of facilities, technical standards, handling of material, labeling, etc. Control guidelines are mentioned but not in the same detail as in current good laboratory practice (GLP). These rules state that all documentation of analytical methods should fulfil certain performance criteria, that

instruments should have maintenance records, and that their performance and those of the method should be documented. Every analyst should in principle document an analytical method and its aims.

Since the late 1970s various leading drug regulatory bodies such as United States Food and Drug Administration (USFDA), World Health Organization (WHO) and Commission of Pharmaceutical Manufacturing Product (CPMP) of the European communities, in consultation and collaboration with various research organizations and industries, have been monitoring the efficacy of various drugs. The Centre for Drug Evaluation and Research (CDER) in the USA is one of the leading agencies which issues timely guidance as regard to various current GMP norms, formulation designs, and bioequivalency.

Owing to the stringent regulatory and ethical requirements, it becomes equally important to monitor the quality of drug substances with respect to their identity, potency, purity (including chiral purity), and dosage at the time of release and at various stages of shelf life. These are achieved through analytical techniques. The analytical results form the basis of the evaluation of drugs and pharmaceutical products, demonstrating their quality, efficacy and safety during drug development and product registration, and verifying their quality in QC process. Rapid and cost-effective provision of suitable results are, therefore, a fundamental challenge in pharmaceutical analytical chemistry.

Analytical methodology is in a period of transition due to technological advances and modified policies of the governmental regulatory agencies. In many countries the regulations and the practices of drug manufacturing have changed because of the recently developed ability of analysts equipped with modern instrumentation to determine low concentrations of impurities. Although HPLC is the method of choice, HPTLC is becoming increasingly popular in the field of pharmaceutical analysis.

6 VALIDATION AND QUALITY ASSURANCE

6.1 Analytical Method Validation

Analytical method validation is a summary of several validation steps involving exact proof and evaluation of the suitability, correctness, and precision of each chromatographic and nonchromatographic step and of the instrumental components. Regulatory recommendations have been developed to promote correct analytical method validation through ICH (International Conference for Harmonization) guidelines, and several articles have been published covering TLC.\(^{(15,16,19,24,62,63)}\)

Table 4 summarizes the validation parameters specific to planar chromatography for pharmaceutical analysis. Errors originating from sample preparation, application, calibration, etc. are evaluated and the selectivity of separation and peak purity are checked. If pure standards of each analyte are available, the information may be obtained by carrying out chromatographic analysis of each standard separately under the predetermined experimental conditions. Assessment of peak purity is best performed by subjecting samples to appropriate stress conditions in order to produce decomposition products; peak overlapping may then be more easily recognized. The chromatograms of treated and untreated samples either unspiked and spiked with known concentrations of impurity standards are recorded at two or three preselected wavelengths. Any change in peak shape resolution, or peak symmetry, determined by comparing the chromatograms obtained from treated and untreated samples,

can indicate nonhomogeneity of a chromatographic peak. Peak homogeneity can also be investigated by two-dimensional chromatography using a different mobile phase in the second direction to the first direction of mobile-phase flow. After trying various mobile-phase compositions during the second run and if single peak chromatograms are obtained the peak can be considered as a pure one.

The ruggedness testing of HPTLC is performed by three different analysts trained in HPTLC, analyzing the same sample under the same experimental conditions to determine problems with reproducibility of the method. Various experiments to be performed for testing HPTLC ruggedness are tabulated in Table 5. The results of evaluation are reported as a percentage of the RSD. A TLC method is judged to be rugged when the system still yields acceptable RSD results in all variations and it passes the system suitability test (Tables 6 and 7). Any parameters favorably influencing the result must be reported and the degree of control must be specified.

6.2 Quality Assurance of Experimental Data and Documentation

QA of the experimental data is an important topic in method validation. If the results of the method validation fails, the QA function rejects the analytical results giving instructions to the analyst to repeat the method developed. The second function of QA includes the documentation activities of the method validation, such as

• compilation of the validation package;
• creation of standard operating procedures (SOP) for satisfactorily validated analytical methods according to GLP requirements;
• statistical assessment of the methodology.

To demonstrate adequate performance of the TLC system, all results must be documented and criteria formulated that should be controlled prior to the use of the TLC system (system suitability test). The necessary items for documentation are as follows:

1. Listings of:
   (a) all samples used for the experiments including sources, lot numbers, analytical results, and storage conditions;
   (b) all required instrumentation used, together with their manufacturing companies and model numbers;
   (c) all necessary reagents used for sample preparation, their required dilutions or mixtures, and storage conditions indicating shelf life;
   (d) all materials and reagents used for mobile-phase preparation including their required dilutions and mixings in detail;
   (e) type, particle size, dimensions, and thickness of chromatoplates used;
   (f) type and size of chamber used for the experiments, experimental conditions such as sample applications, temperature, saturation, developing distance, etc.;
   (g) visualization techniques including detailed description of preparation of spraying reagents, spraying conditions;
   (h) detection parameters.

2. Detailed description of the entire analytical process including sample preparation, standard preparation and step-by-step procedure (including any presaturation, preequilibration, weights, volumes, extraction times, solvent range adjustments, centrifugation times), method for evaluation and calculation.

4. Degradation scheme for the active ingredients and for formulations.

5. All validation data, including definitions, determinations and calculations for the analytical performance parameters, together with densitograms.

6. Proposed criteria for system suitability test.

7. Methods reported as properly written SOPs in detail.

8. Detailed evaluation of the test method validation procedures containing all of the recommendations and precautions to be taken into consideration when the TLC method is being routinely used; some recommendations should be given as to when and why revalidation might be necessary.

7 METHOD DEVELOPMENT

Method development, which results in sufficient separation, is one of the most critical steps of qualitative and quantitative planar chromatography. The main steps involved in method development of HPTLC for pharmaceutical analysis are:

1. selection of the stationary phase
2. selection of the vapor phase
3. selection of suitable solvents
4. optimization of the mobile phase
5. selection of the development mode.

7.1 Selection of the Stationary Phase

Silica gel is the most widely used stationary phase for pharmaceutical analysis. Modified and chemically bonded phases are also used. Practically all stationary phases used in normal-phase and reversed-phase HPLC are now available for TLC.

Precoated TLC or HPTLC plates 20 x 20 cm in size with aluminum or polyester supports are usually employed, mainly for economic reasons. These plates can be cut to size and shape to spot a particular analyte using scissors. Prewashing of chromatographic plates is an essential step. After washing, the plates must be dried for a sufficient time to ensure complete removal of washing liquids in a drying cupboard, by keeping them between two blank glass plates. The washed plates should always be stored in a dust-free atmosphere under ambient conditions, preferably in desiccators without the use of grease for sealing and any drying agents. Prewashing of plates must be done to at least 1–2 cm longer than the subsequent chromatographic development so that any dirt accumulated at the front does not interfere with the densitometric scanning. Methanol is the most commonly used prewashing solvent. Mixtures of chloroform in methanol (1:1), ethyl acetate in chloroform (1:1), and chloroform–methanol–ammonia (90:10:1) have also been used as solvents for prewashing. Methylene chloride–methanol (1:1) is best suited for removing impurities picked up during storage in the laboratory. One may also use 1% ammonia or 1% acetic acid in methanol for prewashing.
7.2 Selection of the Vapor Phase
Selection of the vapor phase is a variable offered in planar chromatography. The type of chamber used decides the vapor phase. Basically there are two types of chamber. In normal (N) chambers there is a distance of more than 3 mm between the layer and the wall or between the layer and the lid of the chamber in the horizontal development of the chromatographic tank. If this distance is smaller the chamber is said to have the sandwich (S) configuration. For saturated and unsaturated systems both these chambers can be used. Characterization of the chamber saturation is done by the marker dye test, as proposed by Nyiredy et al.\(^\text{(64)}\) The time required for chamber saturation depends upon the nature and composition of the mobile phase and layer thickness. When dealing with solvents of low polarity, such as aliphatic hydrocarbons, toluene, and their mixtures, preloading of the dry layer with solvent vapors should be avoided. However, preequilibrium is often recommended for high-polarity solvents such as methanol. Development in a nonsaturated or partially saturated atmosphere is recommended with solvents used in a composition leading to phase separation, such as mixtures of n-butanol, water, and glacial acetic acid. However, in the case of reversed-phase thin-layer chromatography (RPTLC) it is always preferable to saturate the chamber with methanol. If chromatographic separation is to be carried out at a controlled relative humidity of the chamber, then a suitable liquid is placed in a separate device prior to inserting the plate in the tank. The relative humidity of the room is usually controlled by a dehumidifier. However, if experiments are to be carried out at specific relative humidity, then a solution of sulfuric acid or salt solutions may be employed. Twin-trough chambers are suitable for all developing techniques and comparatively smaller volumes of the mobile phase are required.

7.3 Selection of Suitable Solvents for the Mobile Phase
The use of poor-grade solvents in preparing the mobile phases has been found to decrease the resolution, spot detection, and \(R_f\) reproducibility. The mobile phase composition is generally selected by a controlled process of trial and error, based on experience in the field. The mobile phase should be chosen taking into consideration the chemical properties of analytes and the sorbent layer. The basis of the strategy for solvent selection is the solvent classification by Snyder\(^\text{(65)}\) who classified more than 80 solvents into eight groups for normal-phase chromatography according to their properties as proton acceptors, proton donors, and their dipole characteristics. From these eight groups 29 solvents were chosen which are called neat solvents and used in planar chromatography. An efficient method of screening a large number of neat solvents has been described by Birkinshaw and Waters.\(^\text{(66)}\) With automatic CAMAG TLC Sampler III the same sample solution is applied spot-wise in a pattern on an HPTLC plate. Thereafter, 45 \(\mu\)L of different solvents are applied to the same positions at a high dosage rate (500 nL/s\(^{-1}\)) so that circular chromatograms develop. From the position and sharpness of the fraction rings formed, conclusions can be drawn as to the suitability of the solvents. From the solvents showing good separation, their homologs or other solvents of the same group may be tested. Consequently the structure and the properties of the compounds to be separated do not have to be known for these experiments. After these experiments the solvents giving the most appropriate separations are chosen for further optimization of the mobile phase.

7.4 Optimization of the Mobile Phase
Mobile-phase composition is highly important in planar chromatography. Since the early days of chromatography considerable effort has been devoted to optimization because of the specific problems encountered in liquid chromatography. The widespread availability of computers has been of assistance for both liquid chromatography and TLC.\(^\text{(67,68)}\) Optimizing the mobile-phase composition for HPTLC consists of four levels of operation.

7.4.1 First Level
Neat solvents from different selectivity areas are tested as described above for solvent selection. If acceptable resolution in the medium \(R_f\) range is achieved here, the operator can proceed directly to level three with these solvents, i.e. the investigation of solvent mixtures. If this is not the case, level two must be followed.

7.4.2 Second Level
Solvents that leave the main fractions near the start or move them close to the front need to be adjusted in strength. If the \(R_f\) values are too high, the solvent strength is decreased by adding \(n\)-hexane or toluene or, if they are too low, the solvent strength is increased by the addition of water, methanol, or ethanol, usually in the ratio of 9:1 or 8:2.

7.4.3 Third Level
At this level mixtures of solvents from different selectivity groups are investigated by adjusting strength, if required. These solvent mixtures can be binary, ternary, or even quaternary. It is best to start with the center and outside selectivities, i.e. using binary mixtures in the ratios 1:1, 9:1 and 1:9, or ternary mixtures in the ratios...
1:1:1, 8:1:1, 1:8:1, and 1:1:8. At this (third) level addition of small amounts of acidic (acetic acid) or basic (triethylamine) modifier can be considered and tested whenever this appears promising. Also at this level, if not sooner, the operator should work with the developing device to be used later in routine analysis, such as twin-trough, horizontal, or automatic developing chamber.

7.4.4 Fourth Level
At this level final optimization of the mobile phase to be used for a particular separation is made. To obtain the best separation, small variations in the proportions of different solvents may be necessary.

Solvent selection based on experience and chromatographic intuition can be very time-consuming when applied to complex mixtures. For these, more systematic strategies have been elaborated:

- simplex method\(^\text{(69,70)}\)
- prisma model method\(^\text{(71,72)}\)
- window diagram method\(^\text{(73)}\)
- overlapping resolution map method.\(^\text{(74,75)}\)

7.5 Selection of the Development Mode

Ascending linear development is most frequently used for TLC. However, horizontal development has become more common in recent years. Circular development, where the solvent system migrates readily from the centre of the plate to the periphery, is well established for compounds in the lower \(R_f\) range.\(^\text{(76,77)}\) The separation power of the circular development mode is greater than for the horizontal development mode. In the anticircular development mode the solvent system enters the layer at a circular line and flows towards the centre. As the solvent flow velocity decreases with the square of the distance, but the area wetted also decreases as the square of the distance travelled, the speed of the solvent system migration is practically constant. Therefore, this mode is the fastest with respect to separation distance. Anticircular development is a widely accepted approach in analytical TLC if the resolution must be increased within the higher \(R_f\) range.\(^\text{(21)}\)

Of the multiple development techniques, unidimensional multiple development is effective to improve separation in lower \(R_f\) ranges; incremental multiple development improves the zone centre separation; gradient multiple development increases the separation capacity of the chromatographic system; bivariate multiple development is effective for samples of differing polarity. For mixtures of components spanning a wide retention range some form of gradient development is required to obtain even spacing of the developments in the chromatogram. The arrival of the automated multiple development chamber has done much to popularize gradient development in TLC. In a typical automated separation the chromatogram is developed repeatedly in the same direction with successive developments being over increasing migration distances; increments are generally between 1 and 5 mm and a complete program usually comprises 10–30 cycles. Between developments the solvent is drained from the chamber and the mobile phase contained in the layer is evaporated under vacuum. New solvent of any selected composition is then mixed and fed into the developing chamber and proceeds to ascend the layer. All steps are fully automated under capillary flow-controlled conditions – the useful plate length from a separation is limited to above 80 mm, whereas in an optimized separation typical zones have widths of 2–3 mm. Thus the separation capacity for baseline-resolved zones is 25–40, a considerable increase over the separation capacity obtained using conventional development modes.

8 COMPARISON WITH OTHER METHODS

Comparisons of TLC to other chromatographic methods have been reviewed.\(^\text{(78–84)}\) TLC involves the concurrent processing of multiple samples and standards on an open layer developed by a mobile phase. Development is performed usually without pressure, in a variety of modes, including simple one-dimensional, multiple, circular, and multidimensional. The detection of the zones is done statistically with an assortment of diverse possibilities. Paper chromatography is fundamentally very similar to TLC, differing mainly in the nature of the stationary phase. TLC is superior to paper chromatography because it is faster, more efficient, and allows more versatility in the choice of stationary and mobile phases. HPTLC layers are smaller, contain known sorbents with smaller, more uniform particle size, are thinner, and are developed for shorter distances compared to TLC layers. These factors lead to faster separations, reduced zone diffusion, better separation efficiency, lower detection limits, less solvent consumption, and the ability to spot more samples per plate. HPLC involves the elution under pressure of sequential samples in a closed on-line system with dynamic detection of solutes, usually by absorption. The predominant mode of HPLC is reversed phase on bonded silica columns, whereas in normal-phase TLC silica gel is most widely used. The reasons for this difference include the change in properties of silica gel columns caused by continuous mobile-phase flow (which is unimportant in silica gel layers because they are used only once), and the impracticability of using solvents with high percentages of water to develop many brands of bonded reversed-phase layers.
TLC is the most versatile and flexible chromatographic method for the separation of all types of organic and inorganic molecules that can be dissolved and are not volatile. It is rapid because precoated layers are usually used as received without preparation. Even though it is not fully automated like HPLC, TLC has the highest sample throughput because up to 30 individual samples and standards can be applied to a single plate and separated at the same time. The ability to separate samples simultaneously in parallel lanes in TLC is important in applications requiring high sample throughput such as screening of biological fluids for drugs, determining drug residues in animal products, study of drug impurity profiles, etc. Modern computer-controlled scanning instruments and automated sample application and developing instruments allow accuracy and precision in quantification that are in many cases equivalent to HPLC and GC. There is a wide choice of layers and developing solvents (acidic, basic, completely aqueous, aqueous–organic). Solvents that can cause interference with HPLC UV detection can be used in TLC because the mobile phase is removed from the plate prior to detection. Every sample is prepared on a fresh layer, so that problems involved with carryover and cross-examination of samples and sorbent regeneration procedures are avoided. Mobile-phase consumption is low, minimizing the costs of solvents and waste disposal. Because layers are not normally reused, sample preparation methods are less demanding and complex. Also, impure samples can be applied without concern for additional (ghost) peaks and for noneluting compounds that shorten the life of HPLC columns. The wide choice of development methods and pre- or postchromatographic detection reagents leads to unsurpassed specificity in TLC, and all components in every sample, including irreversibly sorbed substances, can be detected.

There is no need to rely on peaks drawn by a recorder or to worry about sample components possibly remaining uneluted on the layer. Being an off-line method, the various steps of the procedure are carried out independently. As an example of the advantage of this approach, zones can be scanned repeatedly with a densitometer using different parameters that are optimum for individual sample components. TLC and HPTLC are cost effective and environment friendly, and the chromatograms can be preserved as well as being photo- or videodocumented.

Clinical Chemistry (Volume 2)
Planar Chromatography in Clinical Chemistry

REFERENCES

The biopharmaceutical market has exploded in the last 10 years, with annual sales easily exceeding a billion dollars per year. Analysis and purification are essential components in the production of therapeutic proteins and peptides, and chromatography is at the core of all pharmaceutical separations. The more popular chromatographic techniques used in the purification of proteins and peptides are reversed-phase chromatography (RPC), hydrophobic interaction chromatography (HIC), ion-exchange chromatography (IEC), affinity chromatography (AC) and size-exclusion chromatography (SEC). In order to meet the challenges of the future it is essential to understand the fundamentals of each technique. In this article an overview of the more popular chromatographic techniques employed to purify biomolecules is presented. Relevant examples are also given and a discussion of detection and scale-up is provided.
population. This approach cannot however be universally applied to other types of viral infection. An example of this is AIDS. Scientists have not yet found a nonvirulent form of the AIDS virus that can be used for vaccination purposes. A possible alternative route that can be used in fighting viruses like AIDS may potentially be found in a specific class of biopharmaceuticals called monoclonal antibodies (Mabs). Mabs are antibodies that have been specifically engineered to target specific types of foreign invaders. For example if a certain species is immune to the AIDS virus, this means that this species must possess the ability to produce antibodies that are capable of neutralizing the virus. If this antibody can be identified, then perhaps genetically engineered microorganisms or transgenic animals can produce it. In principle, when Mabs are introduced to the human host they should protect the human in the same manner that they protect their natural host.

Researchers are also testing the effectiveness of biopharmaceuticals in the treatment of nonviral diseases such as cancer. Surgery, radiation and chemotherapy are three common approaches used to fight this disease. These techniques have helped many patients to extend their lifespan significantly; however, for some cancer patients radiation and chemotherapy produce extremely undesirable side effects. In some cases the chemotherapy and/or radiation do not stop or reverse the progress of the cancer. This has lead biopharmaceutical researchers to look for a better approach. One example of this can be seen in the ongoing research with endosatin and angiostatin. These proteins are specifically designed to constrict the blood flow to cancerous tumors. These and other anticancer biopharmaceuticals are still under investigation. If they do prove to be effective in clinical trials, they should, in principle, produce little or no side effects because of the “task specificity” of protein molecules.

Still another example of the potential of biopharmaceuticals is gene therapy. Gene therapy can be divided into two categories. The first category is somatic cell gene therapy, where the genetic components of certain cells are altered to assist the host in fighting off certain diseases. This alteration is not inheritable by the offspring of the host. The second category is germ line gene therapy, where the genetic material of a fertilized egg is altered. The offspring inheriting these genetic traits are permanently altered. The overall goal of gene therapy is to protect the host from monogenic diseases such as adenosine deaminase (ADA) deficiency, cystic fibrosis, Duchenne muscular dystrophy, polycystic kidney disease, melanoma, neuroblastoma, brain tumors, and many more.

The first biopharmaceutical drug approved by the FDA (Food and Drug Administration) was Humulin, which was developed by The Eli Lilly Company. FDA approval of this drug came in the mid-1970s, 15 years after the discovery of DNA. By 1987 four biopharmaceutical drugs were approved by the FDA, and by mid-1998 approximately 79 biopharmaceuticals were approved for use. Currently, biotech drugs generate over one billion dollars of revenue annually, and the figure is expected to rise sharply.

The production of biopharmaceutical products is linked to the identification of specific genes or receptor sites and genetic engineering technology. Once the desired protein drug has been identified, it is up to the engineering and manufacturing community to produce this drug on a large scale. In a typical biotech process the desired protein is created by genetically engineered microorganisms. If the desired protein resides in the cytoplasm of the microorganism, the cells are ruptured to release the protein into solution. If the protein is soluble, the fermentation broth is filtered or centrifuged to remove excess cellular material. This is usually followed by an enrichment step that could typically involve membrane filtration or extraction. If the protein cannot be adequately purified by these techniques then chromatography is employed as the next step.

Chromatography is at the core of most analytical separations. It has been extensively used in the biotech industry for the purification of proteins and peptides. The popularity of chromatography can be attributed to the versatility of this technique. There are a number of stationary phases that can be commercially purchased. Each stationary phase has the ability to separate analytes by exploiting the differing affinities each analyte has for the immobilized ligands on the stationary phase surface. Additionally, the mobile phase composition and/or pH are key variables that can also be exploited to achieve the successful purification of the desired product.

In this article we will attempt to identify the chromatographic techniques employed in biopharmaceutical processes. Additionally, the use of detectors will be covered and issues relating to scale-up will also be discussed.

2 BACKGROUND

Proteins and peptides are composed of amino acids. The sequence of amino acids dictates the role of a given protein or peptide. In general a peptide has one specific amino acid sequence. A protein on the other hand may have multiple amino sequences and proteins may also possess inorganic compounds, such as iron in the case of hemoglobin. The physical configuration of proteins and peptides also depends on the amino acid sequence. In an aqueous environment each molecule is folded in a manner that forces a preponderance of hydrophobic amino acid
groups to the interior of the molecule and hydrophilic amino acid groups to the exterior of the molecule. The activity of these macromolecules is highly dependent on the physical structure. When a protein or peptide loses its unique structure, it is considered denatured. From an engineering standpoint high temperature and excessive agitation can cause denaturation. Additionally, exposure to certain chemicals and harsh environments can trigger unfolding. An example of a harsh environment would be an environment in which the pH diminishes the activity of the protein. Thus it is essential that the production and purification process conditions be specified in such a way as to keep the structure of these molecules intact.

A general flowchart showing the production and purification of recombinant DNA proteins is shown in Figure 1. The first step in this process is fermentation.
The desired protein manufactured by the cells is either contained internally within the cytoplasm or excreted through the cell wall. If the protein is excreted through the cell wall, the cell lysis (disruption) step is eliminated. Also the recovery of the protein becomes easier because the number of impurities in the bioreactor effluent is far fewer. Many bioprocesses do however require disruption. During cell disruption the desired protein is released into solution along with numerous other molecules that comprise the cell wall and internal structure. Ultrafiltration removes many of the impurities released into solution by disruption. Since proteins are known to adsorb to hydrophobic materials, the membranes used in the clarification process should be hydrophilic in nature to minimize adsorption and permanent denaturation. The filtration process must remove as many impurities as possible. At this point in the process the composition of the solution must be known because chromatography is generally the next step. Accurate knowledge of the feed composition is essential in identifying the type of stationary phase and the operating conditions that are needed to achieve further product purity.

Figure 1 reveals that IEC, AC, HIC and gel filtration chromatography (GFC) are the popular chromatographic options for protein purification. IEC is an obvious choice because proteins are charged molecules and IEC exploits differences in charge to purify biomolecules. HIC exploits differences in the hydrophobicity of proteins. The speed and resolution of this technique is comparable to IEC and SEC. HIC also has additional benefits in that it can remove endotoxins, nucleic acids and viruses from the sample matrix. AC utilizes highly specific immobilized ligands on the stationary phase. These ligands attract molecules possessing similar or complementary moieties. Finally GFC separates proteins and peptides by their size. In GFC the smallest molecules exit the column last and the largest molecules exit the column first.

An example of a plasmid DNA process is shown in Figure 2. This figure again shows chromatography as an integral part of the purification process. In this case the stationary phase will either be an anion-exchange resin or a size-exclusion gel. The selection of the stationary phase generally depends on the nature of the impurities. If some form of adsorptive chromatography is used, it is generally desirable to have the product as the most strongly adsorbing component. With this strategy the impurities will exit the column first. If SEC is used, it is essential that the size differences between the product and the impurities be large enough to achieve a good separation. As previously stated, it is preferable for the desired product to be the most strongly adsorbed. Under this scenario the desired product can be captured with minimal risk of contamination. If the desired product is not the strongest adsorbing analyte then the process designer must ensure that there is adequate resolution between the product and the leading and trailing impurities. A schematic flow sheet of a chromatographic unit operation is shown in Figure 3. It is evident from this diagram that the operator and/or the control system must be aware of everything that is flowing through the system. It is also apparent that good resolution is essential to minimize contamination and maximize yield. The actual time the product tank inlet valve is opened and the amount of time this valve stays open is highly dependent upon the resolution that is achieved by the column.

The heart of the system shown in Figure 3 is the column. The proper selection of the column stationary phase is vital. The selection of the mobile phase can also influence the separation, but the stationary phase undoubtedly has a large effect on the separation. The chromatographic designer must look for physical parameters that distinguish between the product and the impurities. As previously stated, molecular size difference is often used as a means of purifying proteins and peptides. In many other cases molecular charge differences can be exploited, while in other applications differences in solubility and/or hydrophobicity are used to achieve a separation. Affinity can also provide an effective means of achieving purity. One method by which chromatographic designers can explore these physical differences is by collecting capacity factor data for the product and each impurity in the sample matrix. The stationary phase that provides the greatest differential between the product capacity factor and the capacity factors for the impurities is normally chosen for plant operations. Another way of obtaining the same data is to produce pure component isotherms. The quantity of material required for these experiments may be an issue; however, it is important to note that isotherm data are critical because the capacity factor approach is not adequate when the chromatographic system is overloaded, as is the case in many pharmaceutical applications. Components with the greatest attraction for the stationary phase will also have the highest loading. The stationary phase that demonstrates the greatest differential between the product loading and impurity loading will normally be chosen for plant operations. The former method is currently the most popular, because correlations have been developed that relate the capacity factor to peak resolution. These correlations also allow designers to estimate column length for scale-up.

An overview of the various stages of protein fractionation is shown in Table 1. In the initial fractionation step the main goal is to capture and concentrate similar

species into groups. The goal of intermediate fractionation is to separate the components that were concentrated into groups in the initial stage. The final stage is polishing. The goal here is to attain the required purity as specified by the FDA. As seen in Table 1, the various modes of chromatography that are commonly employed in protein and peptide purification are reversed phase, hydrophobic interaction, ion exchange, affinity and size exclusion. These techniques that are used to purify peptides and proteins in pharmaceutical applications will be discussed in the next sections. Because of the competitive nature of the pharmaceutical business, pharmaceutical companies rarely publish articles describing their process capabilities. Therefore the examples cited in this article come from research articles that have been published in key scientific journals.

3 APPLICATIONS

3.1 Reversed-phase Chromatography

RPC is the most popular form of chromatography used in the purification of pharmaceuticals. The popularity of this technique is due to its flexibility. In RPC the column is packed with a nonpolar stationary phase. The solute is brought into contact with the stationary phase by a polar mobile phase and is eventually displaced from the stationary phase with a suitable solvent. The main role of RPC in the biopharmaceutical industry is in the purification of polypeptide mixtures. RPC is well suited to handle very complex mixtures of polypeptides. This is because a number of parameters such as pH, temperature, mobile phase composition and solvent gradient can all be adjusted to obtain the desired product in a highly purified state. This type of flexibility underscores the popularity of this technique.

The separation of components in RPC is primarily achieved by differences in solute hydrophobicity and solubility. The mobile phase is usually an aqueous buffer that contains ion-pairing agents such as trifluoroacetic acid (TFA). In most applications the ion-pairing agent is added to buffer in low concentrations to assist in solubilizing hydrophobic macromolecules such as large polypeptides. The stationary phase in many RPC applications usually contains n-octadecyl, n-octyl or n-butyl moieties bonded to the support. These stationary phases are all hydrophobic in nature with n-octadecyl being the most hydrophobic and n-butyl being the least hydrophobic. The particles comprising the stationary phase are highly porous. The average particle diameter ranges from approximately 3 µm for analytical columns to 100 µm for preparative columns. A summary of common RPC stationary phases is presented in Figure 4.

The elution of analytes in RPC is accomplished by adding an organic modifier to the mobile phase. Typical organic modifiers that are commonly used are acetonitrile, isopropanol, ethanol and methanol. The solubility of each analyte in the “eluting” mobile phase is also a key factor because the elution order of each analyte is a function of the mobile phase solvent strength. The solvent strength of the mobile phase depends on the type and concentration of the organic modifier used. In a typical application, analytes are desorbed from the stationary phase by a linear gradient in which the concentration of the organic modifier is linearly increased. When the concentration of the organic modifier reaches a certain level the analyte’s affinity for the mobile phase becomes greater than its affinity for the stationary phase. In other words when the solvent strength reaches a certain level it is thermodynamically more favorable for the analyte to be in the mobile phase than adsorbed to the surface phase. Therefore subtle differences in solubility can be exploited to provide adequate separation and purification of sample mixtures.

A number of mathematical models describing RPC have been published. Among the most common are the solvophobic theory(10) and the stoichiometric displacement model (SDM).(11) A detailed description of each theory is beyond the scope of this chapter and the reader is

referred to the references cited for a detailed description. It is however useful to outline the simplest of these models briefly, the SDM. This model is based on the premise that when a solvated molecule is adsorbed by the adsorbent, a stoichiometric number \( Z \) of solvent molecules are released at the interface between the adsorbent and the solute. This SDM equation for the equilibrium constant \( (K) \) in RPC is shown in Equation (1):

\[
K = \frac{P_b[D_o]^Z}{P_m[L_d]^Z}
\]

where \( P_b \) and \( P_m \) are the adsorbed protein concentration and unbound protein concentration, respectively, \( D_o \) is the solvent concentration and \( L_d \) is the ligand density. The reported expression for the capacity factor is (Equation 2):

\[
\log k' = \log \left( \frac{1}{D_o} \right) + \log[I]
\]

where \( I = ([L_d]^{[\phi]K})/[D_o]^{[\phi]} \) and \( \phi \) is the phase ratio. If the ligand density and phase ratio are known, the equilibrium constant can be calculated directly. Once \( K \) is known, the linear region of the isotherm can be approximated from Equation (2). In order to approximate the nonlinear portion of the isotherm, activity coefficient data are needed.

Although RPC is widely used in the pharmaceutical industry, it is only used in limited applications for the purification of therapeutic proteins. Typical biopharmaceutical applications that are amenable to RPC are the purification of polypeptides and small proteins that tend to be mildly hydrophobic in nature. The limitations are primarily due to the problem of denaturation. Proteins and certain polypeptides have unique three-dimensional structures. When proteins with strong hydrophobic interiors are brought into contact with a strongly hydrophobic stationary phase, the protein will rearrange its structure to allow the hydrophobic interior to have maximum exposure to the surface. If the hydrophobic patches have a strong affinity for the stationary phase, irreversible adsorption can sometimes occur. If irreversible adsorption does not occur some proteins can still be permanently denatured. In either case, these effects lead to low recoveries or insufficient purification (mixture of active and denatured protein). Insufficient purification is usually denoted by the presence of very broad peaks in the chromatogram.

An example of the effect of protein hydrophobicity in RPC is seen in Figure 5. In this figure the chromatograms of three different proteins of increasing hydrophobicity from (a) to (c) are presented. These results were obtained using 5-\( \mu \)m C4-silica particles in a 250 × 4.6-mm internal diameter (ID) column. The least hydrophobic protein, ribonuclease A, is shown in Figure 5(a). This chromatogram is described as being “good”. This is because of the symmetrical shape of the peak and a recovery that exceeds 80%. Figure 5(b), which is labeled “bad”, is for alcohol dehydrogenase. This peak may indicate conformational changes and is labeled “bad” because in this application wide protein peaks in RPC are usually the result of conformational changes. Figure 5(c) is \( \beta \)-galactosidase. The peak shape for this protein is labeled “ugly” because it is extremely broad with multiple bands present.

The hydrophobicity of 33 example proteins and peptides is presented in Table 2. This table indicates the appearance of a relationship between the hydrophobicity of a protein and the quality of the RPC chromatogram. Some exceptions to this general relationship are also apparent. For example carbonic anhydrase (hydrophobicity = 129) yields a good chromatogram while \( \beta \)-lactoglobulin (hydrophobicity = 127) yields a bad chromatogram. Perhaps an interesting experiment would be to rank the peak shapes against their heats of adsorption. This type of experiment could possibly explain these inconsistencies.
A good example of the ability RPC has in resolving polypeptide mixtures is shown in Figure 6. One of the objectives of this work was to determine if reversed-phase high-performance liquid chromatography (RPHPLC) could be used in identifying polypeptide variants in hemoglobin. Hemoglobin has six polypeptide chains. The chromatograph of normal polypeptide chains in hemoglobin is shown in Figure 6. Figure 7 shows the chromatograms of individuals with variant β-chains. This example plus others reported by Huisman indicate the utility and reliability of RPHPLC. This method cannot however be used to predict which mutant is present although it can nonetheless indicate the presence of an abnormality.

Another example of the ability of RPHPLC to resolve polypeptide mixtures is shown in Figure 8, for the separation of human growth hormone variants. The results here demonstrate the previously mentioned effect of solubility on resolution. Each variant (a, b and c) had slightly different solubility in the mobile phase solvent.

The difference, although very slight, was significant enough to be amplified by RPC.

The separation of five peptides ranging in size from 2 to 14 amino acid residues is shown in Figure 9. Unlike the previous two examples these peptides were eluted under isocratic conditions using a phosphoric acid buffer at pH 3. Isocratic conditions indicate that the mobile phase composition is constant. Under isocratic conditions the separation is dependent upon the difference in the distribution coefficients for each analyte. Additional examples of protein and peptide purification with RPC can be found in the work of several authors. Additional information and references discussing the use of RPC in purifying proteins and peptides can be found in Aguilar and Hearn.

### 3.2 Hydrophobic Interaction Chromatography

HIC has become a popular technique used in the purification of proteins. HIC separates sample components by exploiting differences in hydrophobicity. This is the same principle employed by RPC; however, there are some significant differences. The first difference is that HIC usually takes place in the presence of salt. Solvents such as organic modifiers are not commonly used. The second difference is that the stationary phases in HIC are not as hydrophobic as in RPC. The ligand density is lower and the molecular structures of HIC ligands are slightly different. Since the hydrophobicity of the stationary phase is lower, the risk of protein denaturation is also lower. This reduction in hydrophobicity also reduces (not eliminates) the affinity of the protein for the stationary phase. This phenomenon has been in evidence in studies focusing on the energetics of adsorption. In these experiments it was shown that the ΔH value associated with the adsorption of proteins on reversed-phase supports is exothermic. This is indicative of the fact that proteins, in particular the more hydrophobic proteins, will have stronger affinities for the stationary phase. This also explains why certain proteins irreversibly adsorb to reversed-phase supports. It is simply more energetically favorable for the protein to remain on the surface than to become solubilized in the mobile phase solvent. Similar studies were also conducted on hydrophobic stationary phases. The results revealed that in this case of HIC protein adsorption was entropically driven. The reported ΔH values associated with adsorption were endothermic. From the standpoint of energetics, HIC appears to be a milder process. This milder nature may be the underlying reason why HIC is generally better suited to protein purification than RPC.

In HIC, protein elutions are usually accomplished through linear salt concentration gradients. The presence of salt has a great influence on the equilibrium behavior...

### In HIC

It has been postulated that the equilibrium distribution in HIC is a function of the preferential interactions between the protein, the salt and the water. The free energy of a dissolved protein will increase when a salt such as NaCl is added to the solution. As a result of the presence of salt the protein will become preferentially hydrated; hydration excludes salt from the immediate vicinity of the protein. As the salt concentration is increased, the interactions between the protein and salt will also increase. This is because at higher salt concentrations the salt molecules displace some of the water molecules surrounding the protein. The protein, in an effort to reduce its free energy, will adsorb to the surface. The free energy of the protein is effectively reduced because the amount of protein surface area exposed to the salt has been minimized.

The selection of salt is an important decision in HIC separations. This is because the salt will alter the surface tension of water. If the surface tension of water is too high the protein will precipitate out. Once again the underlying reason for this is energetics. The free energy of the protein in the solid phase is lower because the protein–salt interactions are minimized when the protein has precipitated out of solution. A list of the common salts used in HIC with their effects on the surface tension of water is presented in Table 3.
The selection of the stationary phase is also another very important consideration. Although HIC is milder than RPC, protein conformation changes are still possible.\(^{(36)}\) With this in mind, the system designer must carefully analyze the peak shapes of the purified analyte in question. If split peaks are present then a conformational change has occurred. If broad peaks are present then the possibility of a conformational change exists. The word ‘possibility’ is used because broad peaks can also arise from excessive protein interactions with the stationary phase. If the desired protein has undergone a conformational change then the resulting effect will be a lower recovery. Examples of commercially available HIC stationary phases\(^{(5)}\) are presented in Figure 10. Additional examples can be found in Neuere.\(^{(9)}\)

As previously stated, the speed and resolution of HIC are comparable with IEC. HIC is also advantageous because of its ability to remove endotoxins, nucleic acids and viruses from certain samples.\(^{(15)}\) Also, as previously mentioned, the risk of denaturation is much smaller than RPC, and the use of harsh solvents for the purposes of elution are generally not required for most HIC applications.

A number of models describing HIC have also been published.\(^{(37,38)}\) One such model is the preferential absorption at 220 nm.

---

**Figure 6** Chromatogram of normal polypeptide chains in hemoglobin. Column dimensions: 300 × 4.6-mm ID. Column stationary phase: Vydac C4 RP (Separations Group, Hesperia, CA, USA); Developer A: 80% water, 20% acetonitrile (CAN) and 0.1% TFA. Developer B: 40% water, 60% CAN and 0.1% TFA. Elution was accomplished by reducing developer A from 51% to 40% over 50 min. This step was followed by a further reduction in developer A from 40% to 20% over 40 min. The column was then purged with developer B for 10 min and equilibrated with 51% developer A. The flow rate was 1.0 mL min\(^{-1}\). (Reprinted from T.H.J. (Reprinted from G. Teshima, E. Canova-Davis, ‘Separation of Oxidized Human Growth Hormone Variants by Reversed-phase High-performance Liquid Chromatography: Effect of Mobile Phase pH and Organic Modifier’, J. Chromatogr., 625, 207–215, 1992,\(^{(14)}\) Copyright 1992 with permission from Elsevier Science.)
Adsorption process in HIC is described by the stoichiometric Equation (3):

\[ pP + sS \rightleftharpoons cC \]  

where \( P \) is the protein, \( S \) is the surface site and \( C \) is the protein–ligand complex, and the variables \( p, s \) and \( c \) represent the number of water molecules associated with each entity in the equation, then the equilibrium constant for this process can be formulated as Equation (4):

\[ \ln K_{obs} = c \ln(m_C) - p \ln(m_P) - s \ln(m_S) \]  

where \( m \) represents the molal quantities of \( P, S \) and \( C \). From the preferential interaction model, the equilibrium can be defined by Equation (5):

\[ \frac{\partial \ln(k')}{\partial \ln(m_3)} = \frac{\Delta v_+ + \Delta v_-}{g} - \frac{n \Delta v_1}{m_1 g m_3} \]  

where \( \Delta v_1 \) is the net displacement of water molecules, \( (\Delta v_+ + \Delta v_-) \) is the net change in modulator ions, \( m_3 \) is the modulator concentration, \( m_1 \) is the water concentration, \( n \) is the total number of cations and anions per formula unit, and \( g \) is the change in the \( \ln(m_3) \) per change in the \( \ln(m_1) \), where \( a \) is the activity of the modulator. Integration of Equation (5) leads to Equation (6):

\[ \ln(k') = c + \frac{\Delta v_+ + \Delta v_-}{g} - \frac{n \Delta v_1}{m_1 g m_3} \]  

where \( c \) is an integration constant. From this model the number of displaced water molecules can be calculated. From these data an estimate of the required area for one protein molecule to adsorb on a given surface at a given modulator concentration can be made. This may provide a potential insight into determining the

Preferential interaction analysis has been used to study protein stabilization and precipitation. If the adsorption process in HIC is described by the stoichiometric Equation (3):
degree to which conformation changes are occurring. Once these data have been collected under certain conditions, they can then be used to estimate retention and changes in retention with respect to changes in modulator concentration.

An example of the resolving power of HIC is presented in Figure 11, which shows the separation of two RNase variants. These variants were produced by deamination at position 67 of RNase. One derivative contained ASP (aspartyl) and the other iso-ASP. As seen in Figure 11, these molecules were eluted with a linear gradient that effectively lowered the salt concentration. As previously stated, lowering the salt concentration will lower the surface tension of the water. The surface tension is eventually lowered to a point where it becomes energetically favorable for the protein to interact with the water molecules rather than the surface.

Another example of protein purification using HIC is presented in Figure 12. These results were collected on an HIC monolith column. The advantage of a monolith is that the contact surface area of the stationary phase is significantly increased. Figure 12 shows that all of the components were resolved in less than 4 min. This separation was carried out in a 50 x 8-mm ID column. The effect of salt on the system is the same as described in the previous example.

A third example showing the usefulness of HIC is shown in Figure 13(b). One of the three large peaks shown in Figure 13(b) is purified Mabs. In this example the HIC column was preceded by an ion-exchange column. The chromatogram from the ion-exchange column is shown in Figure 13(a). The shaded area in Figure 13(a) gives the approximate location of the Mabs. Ion-exchange column fractions from 18–24 min were collected and injected into the HIC column. This produced the chromatogram shown in Figure 13(b); the shaded portion indicates the location of the purified Mabs. At the time this experiment was performed, the accepted way of purifying Mabs was by precipitation induced by the presence of ammonium sulfate. The disadvantage of precipitation is that a portion of the protein is normally lost. This experiment demonstrated the use of chromatography as a viable means of purification with minimal losses in protein activity. Additional examples of the resolving power of HIC can be found in the work of several authors.

Additional references and information on the use of HIC in the purification of proteins can be found in Cooke et al. and Shansky et al.

3.3 Ion-exchange Chromatography

IEC is the most common technique employed for protein purification. IEC exploits differences in protein charge...
to purify mixtures. Proteins are essentially very large electrolytes. Adjusting the solution pH to a value that is different from the protein’s pI (the pH at which the protein is neutral) can alter the charge of a protein molecule. If the solution pH is above the pI of the protein, the protein will possess a net negative charge. Likewise the protein will possess a net positive charge when the solution pH is less than the pI. In IEC the stationary phase will have the opposite polarity of the desired protein. In general a weakly charged protein sample will require a strongly charged stationary phase to resolve the mixture. Strongly charged protein samples will usually require a weakly charged stationary phase to resolve the mixture. If a strongly charged molecule is brought into contact with a strongly charged stationary phase, the molecule could be irreversibly adsorbed. If the proteins and the stationary phase are too weakly charged, sample resolution will not occur. It should be noted that protein adsorption in IEC can be enthalpically or entropically driven. The ΔH of adsorption depends on the pH, the salt concentration and the stationary phase.\(^ {47-50}\) Thus it is possible to adsorb a protein with a net positive charge on an anion-exchange column, if the conditions selected result in an entropically driven process.

Like HIC, ion-exchange separations take place in the presence of aqueous buffers and salt. Buffers are important because their presence stabilizes the mobile phase pH. The choice of a buffer usually depends on the operating pH. Ideally, the pK\(_a\) of the buffer should be as close to the operating pH as possible. Some typical IEC buffers are found in the Pharmacia Biodirectory.\(^ {51}\) The presence of salt does however serve a different purpose in IEC. The salt acts as a displacing agent in IEC. For example in the case of an anion-exchange column the salt anions exchange with negatively charged proteins on the surface. In IEC the stationary phase, solution pH, column temperature and salt concentration are key design parameters. Some typical ion-exchange stationary phases are shown in Table 4.\(^ {52}\)

The stoichiometric equation describing the ion-exchange process is shown in Equation (7):

\[
Z_n C_p + Z_p N_p \Leftrightarrow Z_n N_p + Z_p C_n
\]

where \(C_p\) and \(N_p\) are the protein concentrations in solution and on the surface respectively. \(C_n\) and \(N_n\) are the respective concentrations of the salt counterion in solution and salt counterion on the surface. \(Z_p\) is the effective protein charge, and \(Z_n\) is the charge of the salt counterion.

Figure 13 Separation of Mabs using IEC and HIC. The chromatogram of the ion-exchange column is shown in (a). The shaded area in (a) represents the approximate location of the Mabs. An aliquot from the ion-exchange column fractions from 18–24 min was injected into the HIC column producing the chromatogram shown in (b). The shaded area in (b) represents the location of the Mabs. HIC column dimensions: 75 × 7.5-mm ID; HIC stationary phase: TSK gel Phenyl 5 PW. HIC column equilibration: buffered solution containing 0.030 mol L\(^{-1}\) Tris-HCl and 1.0 mol L\(^{-1}\) sodium sulfate (pH 7.5). Elution was accomplished by reducing the ionic strength and the polarity of the mobile phase with a linear gradient for 80 min. The final salt concentration was 0 mol L\(^{-1}\) and the mobile phase contained 5% 2-propanol. The flow rate was 1 mL min\(^{-1}\). The sample load was approximately 0.3 mg of protein. A thermodynamically consistent model that has been developed to describe the equilibrium relationship in Equation (7) is the nonideal surface solution (NISS) model. The NISS equilibrium constant is defined by Equation (8):

$$K = \frac{a_s^z}{a_p^z} \frac{a_n}{x_n}$$

where $a_s^z$ and $a_p^z$ are the respective activities of the protein on the surface and in solution. $a_n^z$ and $a_n$ are the respective activities of the modulator on the surface and in solution. The activity of each species on the surface is defined as the product of $g_i x_i$, where $i$ represents either the protein or counterion on the surface, $g$ is the activity coefficient and $x$ is the mole fraction. The activity of the adsorbed species has been calculated using a model developed by Talu and Zweibel. From Equation (8) an expression for the capacity factor was derived and Equation (9) results.

$$\ln k' = \ln[K\phi] - \frac{z_p}{x_n}[\gamma c_n]$$

where $K$ is the equilibration constant, $\phi$ is ion-exchange capacity of the resin, $\phi$ is the phase ratio, $z_p$ is the protein charge, $z_n$ is charge of the counterion, $c_n$ is modulator concentration, and $\gamma$ is the salt activity coefficient. If the resin capacity and phase ratio are known then Equation (9) can be used to calculate the equilibrium constant $K$ and the protein charge $z_p$.

An example of IEC is presented in Figure 14. In this work 11 egg-white proteins are separated by three methods. The known proteins in egg white are shown in Table 5. The conclusions reached from this experiment were that IEC offered a more complete analysis when compared to RPC or gel permeation chromatography.

Another example of the resolving power of IEC is shown in Figure 15, which shows the separation of six isoforms of ovalbumin using displacement chromatography. In displacement chromatography, the solutes are allowed to adsorb to the stationary phase. The solutes are then displaced from the adsorbent by a displacer, which has a higher affinity for the adsorbent than any of the solutes. This separation exemplifies the enhanced resolution potential that displacement chromatography possesses. An elution separation of the same mixture gave only three isoforms, but six were identified with displacement chromatography. Figure 15 illustrates an additional feature of ion-exchange displacement chromatography. All the isoforms are produced at concentrations substantially higher than the feed. The displacement process leads to concentration as well as separation of the sample components. Additional examples of IEC can be found.

3.4 Affinity Chromatography

An excellent review of AC is presented by Subramanian and highlights are presented in this section. AC is by far the most specific method that can be employed for the isolation of protein molecules. In RPC, HIC and IEC the adsorption process is consistent with the principles of physisorption. The interactions are not necessarily site specific, the heats of adsorption...
Figure 14 Separation of hen egg-white proteins by (a) gel permeation chromatography, (b) reversed-phase chromatography and (c) ion-exchange chromatography. In this application the IEC column was reported to produce the best resolution. IEC column dimensions: 5 × 0.5-cm ID; IEC column stationary phase: Mono Q HR 5/5. The IEC column was equilibrated with 0.02 M Tris-HCl (pH 9.0). Elution of the protein from the IEC column was accomplished by a stepwise gradient that increased the concentration of NaCl. The flow rate was 1.0 mL min⁻¹. (Reprinted from A.C. Awade, T. Efstathiou, ‘Comparison of Three Liquid Chromatographic Methods for Egg-white Protein Analysis’, J. Chromatogr., B, 723, 69–74, 1999, with permission from Elsevier Science.)

are relatively low, and the process is usually rapid and reversible. In AC the interactions between the analytes and the surface ligands are extremely specific. In a more strict sense the interactions are site specific. This is because the stationary phase contains biospecific ligands that exclusively elicit very specific and limited types of interaction. The stationary phase ligands will only interact with specific groups on the protein molecule. This type of specificity is normally seen in chemisorption processes. Note that chemisorption is usually a slow process that takes place at elevated temperatures. In AC the process is usually rapid and typically occurs at ambient temperatures. This technique is used for the purification of highly valuable proteins. It is of particular value when the protein concentration is very dilute.

The principle underlying AC is shown in Figure 16. This emphasizes the biospecificity of the protein–ligand binding. Dilute protein solutions can be concentrated on the order of a 1000-fold. Interferon has been purified on an immobilized antibody column with a 5000-fold increase in specific activity. A list of the overall advantages and disadvantages of AC is shown in Table 6. Of the disadvantages listed, the slow adsorbent development time can potentially be the most difficult obstacle to overcome. This is due in part to the need for biospecific ligands. The search for biospecific ligands can be time-consuming and expensive. Once a ligand has been identified it must be attached to the support without losing its activity. Since proteins are large macromolecules the ligands must be spaced far enough apart to allow the protein–ligand complex to form. Finally, the stationary phase must be validated in a pharmaceutical plant.

Some examples of AC ligands and their target proteins are presented in Table 7. A critical parameter to consider in the selection of an AC ligand is the dissociation constant

Chromatogr.*, 519, 87–98, 1990, with permission from Elsevier Science.)

\[
K_d = \frac{[PL]}{[P][L]} \tag{10}
\]

where PL is the protein–ligand complex concentration, P is the protein concentration and L is the ligand concentration.

The risks of irreversible protein adsorption and denaturation are minimized when the value of \(K_d\) is between \(10^4\) and \(10^6\). At higher \(K_d\) values the risk of protein damage increases. At lower \(K_d\) values the interaction between the protein and surface ligands may not be strong enough to retain the protein.

Once a protein is sufficiently bound to the stationary phase the column is then washed to remove excess debris. After washing, the protein is eluted from the column. Protein elution can be accomplished by varying pH, modulator concentration or possibly the concentration of a specific displacing cofactor or substrate. The latter two options can be cost prohibitive. If these options fail, then chaotropic agents such as urea or ethylene glycol can be used to desorb and elute the protein. It must be noted, however, that these chaotropic agents can be harsh and as a result some proteins can become denatured.

An example of AC is shown in Figure 17, which shows the purification of different types of blood cells. The stationary phase used was PEG 20M-sepharose 6B. The essential chemical structure of the stationary phase is shown in Figure 18. In all of the cases the adsorption of blood cells onto the stationary phase was induced by the presence of salt. This suggests that hydrophobic interactions may have played a key role in adsorption process. Additional information on AC can be found in Narayanan.

3.5 Size-exclusion Chromatography

SEC, sometimes referred to as gel permeation, isolates proteins by using molecular characteristics such as size and/or shape. Molecules with similar molecular weight can be separated by shape or by significant conformational differences. In general the smaller molecules with high diffusivities permeate the matrix of the stationary phase.

while the larger molecules with lower diffusivities tend to be carried through the column by the mobile phase. An overview of this mechanism is shown in Figure 19. This technique is primarily used for desalting, buffer exchange and purification; however, it has also been used to isolate protein conformational changes that have been induced by a harsh solvent or by an extremely hydrophobic stationary phase. GFC can also be used to determine the molecular weight distribution of synthesized molecules.

SEC stationary phases are usually gels. The gel matrix can be composed of individual polymer chains, aggregated polymer chains or combinations of both. Examples of the individual polymer gels would be the dextran and polyacrylamide gels. These gels have a protein exclusion limit of approximately $1 \times 10^6$ for globular proteins. If these gels are loosely cross-linked they tend to be mechanically weak. High-pressure applications could destroy the gel. For preparative applications the more tightly cross-linked gels provide the mechanical strength required for process applications. Agarose gels are an example of an aggregated polymer. Agarose has a high degree of cross-linking which gives it rigidity and mechanical strength. The composite gels are denoted by

their higher pressure limits across a wide fractionation range.

The choice of a stationary phase in SEC is usually driven by two factors. This first of these is the fractionation range of the proteins in question and the process conditions (pressure, sample load, flow rate, etc.). An example of a selection chart is shown in Figure 20. Each solid line corresponds to a different stationary phase. Once the molecular weight of each component is known the distribution coefficient can be determined from the plot. The optimal stationary phase will be the one in which the distribution coefficients are significantly different.

An example of SEC is presented in Figure 21(a) and (b), which show the effect of mobile phase flow rates and sample volume on resolution. As previously stated, one of the main uses of SEC is desalting. In all cases the salt was effectively removed from the sample components. This is because the salt molecules have a much higher diffusivity than that of the proteins. Figure 21 shows that desalting was less sensitive to the operating conditions, however, protein resolution was sensitive to increased flow rates and increased sample volumes. Additional information on SEC can be found in review articles cited in Irvine and Barth et al. Examples demonstrating the ability of SEC to purify biomolecules are given by several authors.

Figure 17 Separation of blood cells. 3.6 Electrophoresis

Electrophoresis was originally developed for the separation of proteins. This technique is used extensively for protein purification on a small scale. Since electrophoresis is primarily limited to small-scale purifications, a brief overview is presented in this section. References are also presented for readers requiring additional information about this technique.

Protein separation takes place in a column with a diameter of 0.5 mm or less and in the presence of an electric field. In a typical application the electric field placed on the column is generated by a negatively charged anode at the inlet and a positively charged cathode at the exit. The degree of separation depends on the charge-to-mass ratio for each protein. The protein molecules with the greatest negative charge will have the highest affinity for the cathode provided that the relative difference in protein molecular weights is small. The positively charged anions will also move toward the cathode because the electroosmotic flow of the buffer is essentially carrying or pushing these molecules through the column. In capillary electrophoresis the mobility of each analyte is a key factor in determining the selectivity. The mobility ($\mu$) of an analyte is related the electric field strength and the velocity by Equation (11):

$$R_s = \frac{1}{2.3} \left( \frac{F}{R_u} \right)$$

Figure 21 SEC protein fractionation studies. Column dimensions: 250 x 9.4-mm ID; mobile phase of 200 mM sodium phosphate, pH 7.0. The flow rate varied from 0.25 to 5 mL min$^{-1}$ in (a). The separation conditions and column were the same in (b) except that the flow rate was held constant at 2 mL min$^{-1}$ and the injection volume was varied from 2 to 200 µL; 1, bovine serum albumin dimer; 2, bovine serum albumin; 3, ovalbumin; 4, lysozyme; 5, sodium azide. Results obtained by changing (a) flow rate and (b) sample size. (Reprinted from R.D. Ricker, L.A. Sandoval, 'Fast Reproducible Size-exclusion Chromatography of Biological Macromolecules', J. Chromatogr., A, 743, 43–50, 1996, with permission from Elsevier Science.)
where \( v \) is the molecule velocity (cm s\(^{-1}\)), and \( E \) is the electric field strength (V cm\(^{-1}\)), and \( \mu \) has units of (cm\(^2\) s\(^{-1}\) V\(^{-1}\)). The electric force \( F_e \) experienced by a given protein molecule is given by Equation (12):

\[
F_e = qE
\]

where \( q \) is the ion charge. The frictional force \( F_f \) for a spherical ion is given by Equation (13):

\[
F_f = -6\pi\eta rv
\]

where \( \eta \) is the solution viscosity and \( r \) is molecular radius. When these forces are balanced, Equation (14):

\[
qE = 6\pi\eta rv
\]

Solving for \( v \) and substituting the result into Equation (13) provides a theoretical prediction for the mobility in measurable terms,\(^{82}\) Equation (15):

\[
\mu = \frac{q}{6\pi\eta rv}
\]

In Equation (15) the mobility is directly proportional to the molecular charge and inversely proportional to the molecular size and mobile phase viscosity. Since the net charge is a function of pH, the mobility of an ion is dependent upon the pH of the mobile phase.

A number of alternative versions\(^{83}\) of electrophoresis are employed when the difference in protein mobilities is small. Isoelectric focusing is a form of electrophoresis that separates proteins by their pl values. A pH gradient is established in the column with a low pH at the inlet and higher pH at the outlet. Capillary gel electrophoresis separates proteins by size. A highly cross-linked polymer is present in the column. The separation is essentially the same as that employed by SEC. Micellar electrokinetic capillary chromatography is another technique commonly used. The method is good for separating proteins with similar charge. A micelle-forming surfactant such as sodium dodecyl sulfate is added to the mobile phase. The more hydrophobic proteins diffuse to the interior while the less hydrophobic proteins stay in the mobile phase. The proteins that diffuse into the micelle have effectively lowered their charge-to-mass ratio, thus reducing their mobilities. The less hydrophobic proteins emerge from the column first while those inside the micelles emerge last.

A thorough review of electrophoresis is presented by the work of several authors.\(^{83–86}\) Examples of the resolving power of electrophoresis can be found in Jorgensen et al.,\(^{87}\) Rabel and Stobaugh,\(^{88}\) and Dolink.\(^{89}\)

## 4 DETECTION OF COLUMN RESPONSE

Detectors are an essential component of any chromatographic process. The output of a chromatographic detector displays a series of peaks that represent either a product or an impurity. Detectors are used in three different applications. These are manufacturing, design and research. In manufacturing, the detector is used to verify if the desired separation or purification of components was successful. In this application the chromatographer is looking for peak resolution. Good peak resolution means the product peaks should ideally be distinct with little or no overlap with other peaks representing impurities or other products.

The second application is in design. Before a column is specified for production a number of experiments are conducted to determine the proper stationary phase and mobile phase composition. The system designer uses data directly from the detector output to calculate peak resolution and the required number of theoretical plates. The resolution between any two peaks can be calculated by the empirical relationship shown by Equation (16):

\[
R_s = \frac{1}{4} \frac{\alpha_1 - k_1}{\alpha_1 + k_1} \frac{1}{N_1^{1/2}}
\]

where \( R_s \) is the resolution between component peak 1 and component peak 2, \( N_1 \) is the number of theoretical plates required for component 1 and \( k_1 \) is the capacity factor for component 1. \( \alpha_1 \) is the ratio of \( k_1/k_2 \), where \( k_2 \) is the capacity factor for component 2. \( \alpha \) is commonly referred to as the selectivity. \( N_1 \) can be further defined by Equation (17)

\[
N_1 = \frac{L}{H} = 5.54 \left( \frac{t_R}{W_{1/2}} \right)^2
\]

where \( L \) is the column length, \( H \) is the height equivalent of one theoretical plate, \( t_R \) is the retention time, and \( W_{1/2} \) is the peak width in time units at half peak height. These two equations show that resolution is a function of peak shape and retention time. All of these data are taken from the detector output and used to specify the column and the method of achieving the desired separation or purification, thus making the detector a key part of the design phase.

In the third application, the detector output can be used as an investigative tool in analytical applications to explore the interaction between a given analyte and a given stationary phase. The peak shape reflects the nature of the interaction between an analyte and the surface. Broad peaks or peaks with long tails are indicative of strong affinities between the analyte and the stationary phase. They can also be indicative of mass
transfer resistance. As previously stated, in RPC broad peaks can also indicate that part of the protein sample has undergone a conformational change. As shown in Figure 22(a) Gaussian-shaped peaks are indicative of linear behavior. \( K \) Here the distribution coefficient for a given component is independent of concentration. Figure 22(b) demonstrates that peaks with sharp fronts and diffuse tails are indicative of Langmuirian behavior. In this scenario the distribution coefficient of a given component decreases when the mobile phase concentration of that component is increased. These peak shapes are typically seen in overloaded preparative applications. Figure 22(c) shows that peaks with diffuse fronts and sharp backs are indicative of anti-Langmuirian behavior. Here the distribution coefficient will increase when the component concentration in the mobile phase is increased. In general detectors are divided into two categories: bulk property detectors and solute property detectors. A thorough review of these detectors is covered by Katz and highlights are presented in this section.

The bulk property detectors sense bulk property changes in the mobile phase solution that contains the solute. These data are compared to a reference that contains pure mobile phase solution. An example of this type of detector is the refractive index detector. This type of detector essentially measures the refraction of light that is passed through a cell containing the solute and the mobile phase. A schematic of this detector is shown in Figure 23. Light is passed through a lens and then through the sample cells. The photocell sensor measures the refraction of light in both cells and records the difference. This value is linearized and then amplified for the output. Refractive index detectors are widely used, inexpensive and simple. The sensitivity of this detector is of the order of \( 1 \times 10^{-6} \text{ g mL}^{-1} \). They are, however, highly sensitive to temperature and pressure changes. Also the use of a reference cell prohibits the use of gradients. These restrictions severely limit the use of this type of detector in protein purification methods.

Another type of bulk detector is the electrical conductivity detector. This detector is both sensitive and linear; however, it is limited to detecting the presence of ionic materials such as organic acids, bases, salts, amino acids and peptides. The detector cell has two electrodes that are energized with an AC voltage ranging from 1 to 10 kHz. When ionic analytes pass through the cell the impedance of the system changes. This change in impedance is then linearized to produce an output that is linearly related to the solute concentration. The sensitivity of this detector is of the order of \( 5 \times 10^{-9} \text{ g mL}^{-1} \).

The second category of detector is the solute property detectors. These detectors sense some chemical or physical property change in the solute. An example of this is the UV (ultraviolet) detector. These detectors pass UV light through the sample cell. The solute absorbs a portion of the light and the remainder of light passes through the cell into a photocell where the signal is measured,
linearized and sent to the output. There are three types of UV detector. The first type is a fixed wavelength detector (Figure 24a). The light source in these detectors emits light at fixed wavelengths. These types of detectors have only limited use in analytical applications because of the presence of a reference cell. As with the refractive index detector, the presence of a reference cell eliminates the use of gradients as a means of eluting products from the column.

The variable wavelength detector is the second type of UV detector (Figure 24b). The light source in these detectors is a deuterium lamp. Deuterium lamps are broad band UV sources that emit UV light at a number of different wavelengths. Light is deflected from two concave mirrors onto a grating. The light is then reflected from the grating onto two concave mirrors in series and then through a plane mirror followed by a lens. The light continues through the flow cell where a portion is absorbed and the remaining unabsorbed light is measured by a photocell. The operating principle is similar to the fixed wavelength detector with two exceptions. First, there is no reference cell, and second the wavelength of the light-emitting source can be changed by rotating the grating. Only one wavelength is passed through the sample, however the ability to select wavelengths allows users to make adjustments for the detection of different products during different runs. Note the major limitation of this detector is that it can only detect sample components that absorb at the wavelength it is configured for. Sample components that absorb light at a wavelength different from the one selected will not be detected.

A third type of UV detector is the diode array detector (Figure 24c). The main difference between this detector and the variable wavelength detector is that multiple wavelengths are passed through the sample and the absorption of multiple wavelengths can be measured simultaneously by the photodiode array. If the sample matrix contains components that absorb light at different wavelengths, detection of each component is possible with a photodiode array. The sensitivity of this detector is of the order of $5 \times 10^{-8}$ g mL$^{-1}$.

Another type of solute property detector is the fluorescence detector. Fluorescence detectors are extremely sensitive instruments. They can detect solutes at dilute concentrations of the order of $10^{-9}$ g mL$^{-1}$. A diagram of a fluorescence detector is shown in Figure 25. Light from a deuterium source is passed through a series of mirrors and ultimately through the sample. A portion of the light is deflected $90^\circ$ through the sample cell wall containing rhodamine which acts as a fluorescence substance. The fluorescent light is detected by a photocell. Only one wavelength can be detected. This type of detector is primarily suited to analytical applications where trace analysis is routinely performed. Since samples are rarely fluorescent, they must be derivatized with a fluorescing agent. The higher cost of fluorescence detectors plus

the additional complications associated with derivatization severely limit the use of these types of detector in preparative protein purification applications. They are, however, used in analytical applications for the analysis of analytes at low concentration or analytes that do not possess a UV chromaphore.

The selection of a detector is as important as the selection of the stationary phase and the mobile phase composition. There are many factors to consider when purchasing a detector. A list of key factors is presented in Table 8 along with a brief description. Other types of detectors such as mass spectroscopy and light scattering are also used in analytical experiments. A review of these types of detectors can be found in Rabel and Stobaugh and Dolink.

5 SCALE-UP

The goal of preparative chromatography is to isolate the desired protein at a purity level that is appropriate for dosing. The objective of scale-up is to reproduce the resolution, analysis time and yield achieved in an analytical scale system. Each of these objectives is influenced by certain parameters in the chromatographic process and therefore a discussion of each is presented in this section.

As previously stated, the resolution is defined by Equation (16). This equation shows the resolution to be a function of the number of theoretical plates, the retention time and the selectivity of the desired component. As seen in Equation (17) the number of theoretical plates is a function of the column length. These equations plainly show that the resolution will increase when the column length is increased. This phenomenon is presented in Figure 26. Since the goal of preparative applications is purification, a longer column appears to be more desirable. Although the longer column in this example produces superior results it is important to note that the analysis time also increases. In analytical applications this may be acceptable because the goal of many analytical separations is to gain knowledge about the composition. On the other hand in preparative applications the analysis time directly affects the operating cost, which in turn affects the product cost. Since the preparative biopharmaceutical market is highly competitive, it is critical that the stationary phase, flow rate, column length, column width and particle size be specified with the underlying goal of producing acceptable resolution while maintaining product throughput.

Particle size and porosity are also important parameters. Smaller porous particles are advantageous because the sample is exposed to more active surface area. Additionally, the diffusion distance is shorter in smaller particles. The enhanced surface area coupled with a shorter diffusion path lays the foundation for a more efficient separation. High efficiency provides the framework
Figure 26 Effect of column length on resolution. This figure shows the comparison of the performance of 5-µm columns of 5, 10 and 15-cm lengths. (a) 5-cm column length, (b) 10-cm column length, (c) 15-cm column length. The data from each run were collected at the same flow rate. (Reproduced by permission of Wiley-VCH, a subsidiary of John Wiley & Sons, Inc., from Uwe D. Neue, *HPLC Columns*, 1997. Copyright Wiley-VCH, 1997.)

Figure 27 Effect of particle size on resolution. Comparison of the performance of columns of constant length but variable particle size. 3 µm × 15 cm; 5 µm × 15 cm; 10 µm × 15 cm. (Reproduced by permission of Wiley-VCH, a subsidiary of John Wiley & Sons, Inc., from Uwe D. Neue, *HPLC Columns*, 1997. Copyright Wiley-VCH, 1997.)

For acceptable resolution. An example of this is presented in Figure 27. Particle type (IEC, RPC, HIC, etc.) and particle size have the largest influence on yield and resolution. There is however a trade-off with smaller particles. As the particle size decreases the pressure drop increases, which results in higher pumping cost. In addition to a higher pressure drop, the friction generated by flow through a tightly packed bed increases the temperature within the column. Increases in temperature alter the equilibrium in such a way that the overall adsorption of the analyte is reduced. Also smaller particles are more expensive.

The combined effect of column length and particle size is shown in Figure 28. Here we see that the maximum resolution is equivalent in all cases. Note that as the column length is increased the maximum occurs at a later time. This figure also shows that the resolution is diminished as the analysis time is increased. This is the result of band spreading within the column, primarily caused by axial diffusion at low flow rates.

The column diameter is another design parameter that must be altered during scale-up to accommodate the increased volume. The effects of column diameter are shown in Figure 29, where increasing the column diameter has a minimal effect on the separation. Because of this it is generally preferred to scale up a system by increasing the column diameter while leaving the length constant. Note that the largest diameter used in this illustration is much smaller than the diameter of generally used preparative columns. It is not uncommon to see preparative columns with diameters of 100 mm. Wider diameter columns can, however, introduce the potential for flow distribution problems. If the sample is not evenly distributed when it enters the column, broad peaks and poor resolution will the result.

In SEC scale-up is achieved by maintaining dynamic similarity, when the analytical column and the preparative column have the same \( L/D = \rho \mu \) values, where
of scale-up experiments can be limited to verifying the once these parameters have been obtained, the number determine the optimum process parameters. In principle, can be reduced. A number of scenarios can be simulated to that the amount of experimentation required for scale-up on ion-exchange supports. The advantage of modeling is of these models attempt to describe protein equilibrium.

Two prominent models that have been reported in the literature for ion exchange are the NISS model developed by Li and Pinto and the steric mass action (SMA) model developed by Brooks and Cramer. Both of these models attempt to describe protein equilibrium on ion-exchange supports. The advantage of modeling is that the amount of experimentation required for scale-up can be reduced. A number of scenarios can be simulated to determine the optimum process parameters. In principle, once these parameters have been obtained, the number of scale-up experiments can be limited to verifying the computer generated results.

Mathematical modeling of protein equilibrium is still in its infancy and more work needs to be done. As modeling efforts continue to develop and improve, our fundamental knowledge of protein—adsorbent interactions will also improve. This increased knowledge will be key in developing purification protocols for future biopharmaceutical products.

### 6 CONCLUSIONS

The arena of biopharmaceutical proteins and peptides has grown into a billion-dollar-a-year business. This market is expected to grow at a faster pace in the next decade, and with growth will come the need to perform thorough and rapid purifications.

Chromatography is at the core of all biopharmaceutical separations. An overview of the more commonly used chromatographic techniques has been presented. From this overview it was shown that RPC is primarily used for the separation of polypeptides and small proteins that are not very hydrophobic. Protein purification is limited in RPC because of the possibility of denaturation. Proteins are large three-dimensional macromolecules that have a number of hydrophobic patches within their structure. If the stationary phase is strongly hydrophobic then irreversible adsorption or permanent denaturation can occur. HIC is better suited to protein purification than RPC because the stationary phase is less hydrophobic. The environment in HIC is milder and protein elution can be accomplished with salt gradients that reduce the ionic strength of the buffer. Because of this the use of harsh solvents is usually not needed. IEC is also well suited to protein purification because of the amphiphilic nature of proteins. Proteins are electrolytic molecules that possess a net charge when the mobile phase pH is either above or below the pI of the protein. IEC exploits small differences in protein net charge to purify mixtures of proteins. AC is used to concentrate valuable proteins that are initially very dilute in solution. The stationary phase in AC elicits specific responses from an analyte. The binding of an analyte with an affinity stationary phase can be thought of in an analogous fashion as a “hand in a glove” or a “key in a lock”. This technique can concentrate the desired analyte over 1000-fold. The stationary phase in AC can be more difficult to synthesize and thus more expensive. SEC is a very popular technique in protein purification. SEC separates proteins by size and/or shape and is frequently used for desalting. Protein detection can be achieved by a number of methods. The most popular detector is the UV spectrometer. Fluorescence, refractive index, conductivity and light scattering are also used but to a lesser extent in preparative

$L$ is the length, $D$ is the diameter, $V$ is the velocity, $\rho$ is the density and $\mu$ is the viscosity. The advantage of dynamic similarity is that the elution profile remains unchanged after scale-up. The dynamic similarity approach may also be applicable to HIC, particularly if the scale-up of an HIC column results in a longer length. This is because a longer residence time in the column could lead to conformational changes in the protein structure. If the preparative column and the analytical column are kept dynamically similar (i.e. identical residence times for the sample), conformational changes can be minimized.

The scale-up process requires a tremendous amount of analytical experimentation. To circumvent this, some researchers have focused on the use of rate models to predict elution profiles. A key requirement of a rate model is that the model must accurately describe the equilibrium. Two prominent models that have been reported in the literature for ion exchange are the NISS model developed by Li and Pinto and the steric mass action (SMA) model developed by Brooks and Cramer. Both of these models attempt to describe protein equilibrium on ion-exchange supports. The advantage of modeling is that the amount of experimentation required for scale-up can be reduced. A number of scenarios can be simulated to determine the optimum process parameters. In principle, once these parameters have been obtained, the number of scale-up experiments can be limited to verifying the computer generated results.
applications. These techniques are more common in a laboratory setting.

Scale-up of chromatographic columns is usually achieved by increasing the column diameter to allow for a higher throughput. The dynamic similarity approach is used in the scale-up of SEC columns. This technique minimizes the analysis time and maintains the peak order and elution times of each product.

As previously stated, the demand for rapid and thorough protein purification will increase as the biopharmaceutical market continues to grow. To meet this need it is imperative that our knowledge of protein adsorption must also grow. It is vital to focus on research that improves our fundamental understanding of the mechanisms governing protein adsorption. As our knowledge in this phenomenon improves, it will be possible to refine existing techniques and create new protocols to meet better the needs of the ever growing biopharmaceutical market.

Pharmaceuticals and Drugs

Quantitative structure–activity relationships (QSARs) are mathematical equations or other types of functions (such as the weights of connections in artificial neural networks) relating chemical structures to their biological activity. The purpose of QSAR studies is to predict novel structures with either beneficial activity as drugs for human or veterinary medicine (bactericides, antiviral or anticancer drugs, and metabolic regulators, such as hypoglycemics, hypotensives, etc.), or selective toxicity for various unwanted higher organisms (pesticides such as fungicides, insecticides, acaricides, weed killers, etc.) Quantitative structure–property relationships (QSPRs) are similar, but the property may be physical or chemical. The main problems involve

1. finding a mathematical representation of chemical structures (usually organic molecules), represented either as molecular graphs by their constitution or connectivity without considering the three-dimensional (3-D) (stereochemical) factors, or as 3-D objects including stereochemical information;
2. measuring the biological activities of a series of molecules;
3. finding the QSAR between each type of biological activity and the most convenient molecular descriptors.

Physicochemical parameters that are closely related to drug transport and ligand binding include lipophilicity, polarity, polarizability, and electronic influence on hydrogen-donor and hydrogen-acceptor binding. The next task is to use the QSAR to predict which novel structures to prepare in order to obtain molecules with the desired biological activity. Then the cycle is usually repeated, because a single pass seldom affords the optimal solution.

The main mathematical descriptors and the techniques for obtaining QSARs are reviewed. An important molecular parameter, which may be measured experimentally or computed from the chemical structure, is lipophilicity or hydrophobicity; Hansch introduced the n-octanol–water partition coefficient as a measure of this property, which, to a large extent, determines the ability of molecules to penetrate the lipophilic, bilayer, extra- or intracellular membranes. Lipophilicity levels that are too high lead to insolubility in water, i.e., it is difficult to administer the drug orally via the digestive tract. The main constitutional and 3-D molecular descriptors are described and examples are given. To be statistically valid, correlations must involve orthogonal or orthogonalized descriptors. Linear, multilinear, and nonlinear types of correlations are reviewed. Screening of virtual combinatorial libraries together with high-throughput combinatorial synthesis and testing provides modern tools for more efficient drug design.
1 INTRODUCTION

A fitting introduction for the importance of analytical chemistry for QSAR in drug design is provided in the following quotation, reproduced with permission:

Over the last two decades the art of drug discovery has changed dramatically with the introduction of new analytical tools. Analytical chemistry revolutionized both the analysis of chemical compounds and the study of biological processes. Today crystallography and NMR (nuclear magnetic resonance) contribute significantly to biostuctural research and have led to the unraveling of many details about the structure and functions of macromolecules, such as nucleic acids and proteins. The second revolution, developed in parallel and which is now indispensable, concerns the use of computers in molecular design and in the lead discovery process.

These phrases, written in 1994 by van de Waterbeemd, must now be supplemented by the contribution brought about by high-throughput analytical techniques, which detect biological activity in minute amounts of substances synthesized simultaneously in combinatorial libraries numbering thousands of compounds. Only a very small number of these substances are then prepared in sufficient amounts for chemical and biological characterization and testing, namely, those that show a positive response to fluorescent, radiochemical, immunochemical, or other analytical techniques. Thus, although the total number of substances registered by Chemical Abstracts is now about 30 million, with an average yearly increase of 0.6–1.0 million, this number will not jump spectacularly with the advent of combinatorial libraries, because only characterized compounds are registered.

It is estimated that before the advent of combinatorial chemistry, for each drug that reached the market, about 5000 compounds had to be synthesized and tested over about 15 years, and thus the cost was US $10^{10}–10^{11}.

It is hoped that both the cost and the duration of new drug launches will be decreased by combinatorial libraries (virtual and experimental) and high-throughput screening, and that QSARs will help to reduce the number of substances that have to be tested.

The vast majorities of novel compounds characterized each year are organic substances with presumed beneficial biological activity, and are synthesized by the major drug companies and by research universities. The necessity of continuously looking for new medicinal drugs originates in a multitude of factors, among which the most important are as follows:

1. the fact that pathogens develop resistance (nowadays few of the “wonder antibiotics” of the 1950s are still useful);
2. the discovery of genetically derived metabolic disorders (the Human Genome Project having completed its task, the complete mapping of the human genome) provides clues for curing such disorders, mainly through computer-aided design of small molecules that can act as receptor blockers or activators for crucial proteins;
3. the need for improving the efficiency of existing drugs learning from the experience of the past, and giving rise to new generations of drugs;
4. developments in the knowledge of biochemical pathways and of the interconnection between the complex networks involved, as well as the opening of new areas such as the mechanisms of memory, neurology disorders, and various forms of cancer.

The huge costs associated with drug discovery, including in vitro and in vivo tests (the latter finalized in lengthy clinical trials), have to be recovered by the drug manufacturing companies during a relatively short time interval under the present patent laws. Insurance companies prefer generic drugs that are less expensive after the patent expires, but very few manufacturers of generic drugs contribute to the research effort.

Computational techniques have now made possible a third type of screening, in addition to the in vitro and in vivo tests, often called in silico tests. Virtual combinatorial libraries, including far larger numbers of structures than can presently be explored experimentally even by the most high-performance combinatorial approaches, can be screened by computers, provided that a sufficient number of reliable experimental data exist to obtain meaningful QSAR studies. An eloquent example is provided by a recent report published by Grassy et al. The activity of the lead immunosuppressive peptide for skin and heart allograft survival in mice was increased about 100 times by a computer-assisted design using 13 molecular descriptors. With 35 natural and nonnatural amino acids that could occupy the seven positions of the relevant portion of the peptidic chain, the virtual combinatorial library would have numbered $35^7 \approx 64$ billion structures. A first filter based on the lipophilicity reduced the number of amino acids to six (one nonnatural and five natural amino acids). All the resulting $6^7 \approx 280,000$ structures were calculated to ascertain whether their 13 descriptors fitted into the favorable domains previously determined from the learning set of about 20 active and inactive compounds. These descriptors, independent of 3-D factors and therefore very fast to compute, are discussed later. Only 26 peptides passed this test, i.e. one in about 10,000, and they were analyzed by molecular dynamics simulations to compare the similarity between their conformational space and that of the active peptides.
1978 references have been selected.

3. TIs have been intensively developed for QSARs and chemometric methods may also profit from this approach.

From the rich literature on QSARs, several post-1978 references have been selected. The literature on QSPRs is almost as rich, and again only a few leading references have been provided. The classical approach to drug design involved the following steps:

1. A known active structure (the lead compound) may be discovered by chance in random screening, by testing many natural products, or in the search for another type of bioactivity (as examples, the erectile activity of Viagra-like compounds was discovered in clinical trials during the search for a hypotensive drug, and oral antidiabetics such as tolbutamide were developed after observing the hypoglycemic activity of new sulfa drugs). Alternatively, enzyme inhibitors may be designed by analogy with enzyme substrates, by the receptor-mapping method, or by Lindquist’s transition state analogs.

2. An exploratory series patterned after the lead compound is generated either by combinatorial chemistry (the preferred contemporary method, when a high-throughput screening is available and when the number of congenic structures is considerable) or by normal stepwise syntheses. At this stage, rational design methods can come into play, as is shown further (Free–Wilson method, extra thermodynamic approach, etc.).

3. On the basis of the bioactivity results of this test series, it is possible to formulate a QSAR using various approaches (molecular descriptors and computer programs, i.e. software) at different levels of sophistication.

4. Finally, on the basis of the QSAR study, it should be possible to predict structures that optimize the beneficial activity of the lead compound, and at the same time minimize the unwanted side effects, most importantly the toxicity.

The ratio between the beneficial and toxic doses is called the therapeutic ratio, and drug designers strive to arrive at structures with optimal therapeutic ratios. (Other unwanted side effects are also important, as shown by the example of thalidomide, which had passed clinical trials and was put on the market in Europe for one year, because at that time no test had discovered that one of its two stereoisomers had severe teratogenic effects.)

Present day paradigms may change the weight and the order of experimental versus computational approaches. The facility of virtual library screening when there is enough experimental material with established bioactivity data enhances the weight of the computer-assisted drug design (CADD) phase. Actually, neither this acronym nor computer-aided molecular design (CAMD) are the best descriptors, and should be replaced by computer-aided ligand design (CALD), as argued by Boyd. CALD is more accurate because computers are not used to design drugs directly, but instead are used to design small molecules (ligands) that may bind specifically to a larger biomolecule, and thus may have a beneficial effect; however, many such ligands have to be tested until a drug is obtained. Combinatorial chemistry techniques also greatly increase the potential for experimental exploration of congeners having the same molecular skeleton (scaffold) and differing in their substitution patterns. In both cases, however, one has to have a lead compound and a test series for an initial QSAR. As a result, one can either explore huge virtual combinatorial libraries and experimentally test only a few compounds, or one can rely on the power of combinatorial synthesis and high-throughput testing to experimentally explore thousands of compounds, and then develop a powerful and very reliable QSAR. In both approaches, several such cycles may be necessary.

Many QSAR data on biological activities have not been obtained with whole organisms or living cell cultures, but with purified enzymes. Often their molecular structure has been determined by X-ray diffractometry in the crystal, or more recently by NMR in solution (with geometry closer to that which is responsible for the catalytic activity of the enzyme). In some cases, the mechanism of this catalytic activity is known in detail. The accuracy and reproducibility of QSAR data for enzyme inhibition are much higher than those of in vivo studies.
3 CHEMICAL STRUCTURE: CONSTITUTIONAL AND STERIC ISOMERISM

3.1 Atomic Bonds

Covalent bonds are the strongest chemical bonds and they hold atoms together in molecules that are unchanged in all three states of matter (crystalline, liquid, and gaseous). Neither phase transitions nor solvation has any effect on such bonds. Ionic and metallic bonds are usually weaker; the former are compensated for in aqueous solutions by ion – dipole interactions so that ions move independently. For ionic or metallic solids, only empirical solutions by ion – dipole interactions so that ions move weaker; the former are compensated for in aqueous on such bonds. Ionic and metallic bonds are usually

Neither phase transitions nor solvation has any effect on such bonds. Ionic and metallic bonds are usually

4. Covalent bonds. Isomers are different compounds that

hold atoms together in molecules that are unchanged in all three states of matter (crystalline, liquid, and gaseous). Neither phase transitions nor solvation has any effect on such bonds. Ionic and metallic bonds are usually weaker; the former are compensated for in aqueous solutions by ion – dipole interactions so that ions move independently. electron groups and "delocalized" or "aromatic" C=C bonds. Four of these isomers are called valence isomers because like benzene they have six CH groups, but the bonding is different. It is customary to classify isomers into constitutional and steric isomers. Constitutional isomers differ in their connectivity patterns, e.g. n-butane and isobutane (which have the common molecular formula C\textsubscript{4}H\textsubscript{10}) have a linear and a branched chain, respectively, of four carbon atoms with single bonds between them. Their constitutional formulae may be written in Smiles notation, which neglects single bonds, as CCCC and CC(CC)C, respectively (when also neglecting the hydrogen atoms, as is usual in molecular graphs for hydrocarbons). Other examples of constitutional isomers are ethanol and dimethyl ether (C\textsubscript{2}H\textsubscript{6}O), which have the hydrogen-depleted constitutional formulæ CCO and COC, respectively; 1-fluoropropane and 2-fluoropropane (C\textsubscript{3}H\textsubscript{7}F), with constitutional formulæ FCCC and CC(FC)C, respectively; and 1-butene and 2-butene (C\textsubscript{4}H\textsubscript{8}) with constitutional formulæ C=C––CC and CC=C–CC, respectively. All such constitutional isomers may be represented mathematically by molecular graphs, where vertices (points) symbolize atoms, and edges (lines) correspond to covalent bonds. In other types of graphs used in chemistry, such as reaction graphs, vertices symbolize chemical species and edges represent elementary reaction steps.

Stereoisomers have the same constitutional formulæ, but differ in the geometrical 3-D disposition of bonds. Steric isomers are of two kinds:

- diastereoisomers or diastereomers, whose properties differ as much as those of constitutional isomers; they are characterized either by differences in distances between nonbonded atoms (e.g. cis/trans or Z/E isomers of polysubstituted compounds with rings such as 1,2-disubstituted cycloalkanes or with double bonds such as 2-butene) or by the presence of several chiral centers and an absence of mirror-image symmetry;

- enantiomers, which are nonsuperimposable mirror images of one another, and whose properties are identical except for those involving interaction with chiral forms of energy (such as plane-polarized photons) or matter (such as chiral solvents and biomolecules or bioreceptors).

Natural compounds synthesized enzymatically by living cells are produced as single enantiomers, whereas chemical reactions carried out in the absence of chiral catalysts yield mixtures of enantiomers (mixtures of equal amounts of two enantiomers with opposite chirality are called racemic mixtures, after the historical discovery by Louis Pasteur in the case of tartaric acids). A tetrahedral carbon atom with sp\textsuperscript{3} hybridization and with four different substituents can have two nonsuperimposable (chiral) configurations leading to
a pair of enantiomers; a pentacovalent atom with trigonal – bipyramidal geometry gives rise to 10 pairs of enantiomers when it has five different substituents; a hexacovalent atom with octahedral geometry affords 15 pairs of enantiomers when all its six substituents are different.

In addition to these types of isomerism, which are seen at normal temperatures because of differences in molecular properties and the possibility of separating isomers, there is also the possibility of conformational isomerism, which does not usually result in isolatable compounds at normal temperatures because of low energy barriers toward rotation around single bonds. However, at lower temperatures, or when rotation barriers are high owing to electronic or steric factors, “rotamers” may become stable enough to be separated.

4 CHEMICAL CODING OF STRUCTURES

For a long time, the Chemical Abstracts Service (CAS) used an extended Morgan algorithm for coding molecular constitutions (connectivity), and more recently a 3-D coding algorithm, CONCORD, has been used. So far, however, parts of the 3-D structures have not been correct in their absolute configuration. The CAS registry number is uniquely associated with a substance or an industrially produced mixture of substances, but bears no relationship to the chemical structure. Linear notation systems (e.g. the Wiswesser line notation) rely on constitutional (molecular) hydrogen-depleted graphs, and 0 otherwise. The result is a symmetrical matrix with \( N \) rows and columns. The sum \( v_i \) over row or column \( i \) is called the degree of vertex \( i \); for instance, a quaternary carbon atom (connected to four other C atoms) has degree \( v_i = 4 \), and a secondary carbon atom has degree \( v_i = 2 \).

More detailed topological information is provided by the distance matrix \( D \), whose entries \( d_{ij} \) represent topological distances between vertices \( i \) and \( j \), i.e. the number of bonds along the shortest path between these vertices. Thus, both matrices \( A \) and \( D \) have zeros along the main diagonal and the same entries 1, but all off-diagonal zeros in \( A \) are replaced in \( D \) by integers that are larger than 1. Sums of entries along row or column \( i \) in \( D \) are called distance sums (distasums) \( d_i \).

Both matrices \( A \) and \( D \) contain all the necessary information to calculate the molecular constitution. TIs have been devised using these matrices as a basis. It had been conjectured that the eigenvalues (EVAs) or characteristic polynomials of \( A \) or \( D \) could uniquely characterize a chemical graph, but this conjecture was proved to be unfounded.\(^{(83)}\)

5 HYDROPHOBICITY OR LIPOPHILICITY PARAMETERS

Historically, the QSAR has its origins in the first attempts (Crum-Brown and Frazer, 1868) to quantitatively connect the biological effects of alkaloids with their chemical structure. In 1893, Richet discovered an inverse relationship between differences in the toxicity of organic compounds and their water solubility. Meyer (1899) and Overton (1901) expressed a correlation between narcotic activity and lipophilicity using oil–water partition coefficients, forerunners of log \( P \) values. Fühner and Neubauer (1906) showed that narcotic activities increase regularly in homologous series, suggesting the additivity of group contributions, a theory which was developed further by Bruce, Kharasch, and Winzler in 1956. Ferguson’s principle, formulated in 1939 at the ICI laboratories, linked the narcotic activity with thermodynamic equilibria governed by the partition coefficient, creating the basis for the development of halothane anesthetics. Further investigations by Albert, initiated in the 1940s, linked the antiseptic activity of acridine derivatives with their ionization equilibria. Zahradnik and Hansen are also considered to be pioneers in this area because in 1960–1962 they applied Hammett’s approach to biological data. Details of references for these early efforts may be found in some of the cited monographs.\(^{(5.31–39,49)}\)

The official birthdate for the QSAR is considered to be 1962, when Hansch et al.\(^{(84)}\) made the connection between biological activities (expressed logarithmically in terms of the molar concentration \( C \) of compounds producing a standard response in a constant time interval) and the octanol–water partition coefficient \( P \) for a substituted

\[ \sum_{i=1}^{N} a_{ij} = 1 \text{ for two adjacent atoms } i \text{ and } j \text{ (i.e. atoms which are connected by a covalent bond)} \]

\[ \sum_{i=1}^{N} v_i = 2 \]
derivative $X-R$ of the parent aromatic compound $H-R$, expressed by analogy with Hammett’s parameters as Equation (1).

$$\log \left( \frac{P_{X-R}}{P_{H11-R}} \right) = \pi_X$$ (1)

Hansch et al.\textsuperscript{[85,86]} then combined two parameters for explaining biological activities, one parameter being the Hammett substituent constant $\sigma$, and the other the lipophilicity, $\pi$ or $\log P$, as shown in Equation (2).

$$\log \left( \frac{1}{C} \right) = k_1 \pi + k_2 \sigma + k_3$$ (2)

On the basis of the observation that there is often an optimal lipophilicity, a parabolic equation in terms of $\log P$ or $\pi$ (Equation 3) was introduced by Hansch and Clayton in the early 1960s and reviewed in 1969.\textsuperscript{[87,88]} They also combined lipophilicity not only with an electronic parameter (Hammett’s $\sigma$) but also with a steric parameter (Taft’s $E_c$ constant, Equation 4), and devised nonlinear relationships in terms of $\log P$ (Equations 5 and 6):

$$\log \left( \frac{1}{C} \right) = k_1 \pi - k_2 \pi^2 + k_3 \sigma + k_4$$ (3)

$$\log \left( \frac{1}{C} \right) = k_1 \pi + k_2 E_x + k_3 \sigma + k_4$$ (4)

$$\log \left( \frac{1}{C} \right) = k_1 \log P - k_2 \log(k_3 P + 1)$$
$$\quad + k_4 \sigma + \cdots + k_5$$ (5)

$$\log \left( \frac{1}{C} \right) = k_1 \pi - k_2 \log(k_3 10^x + 1)$$
$$\quad + k_4 \sigma + \cdots + k_5$$ (6)

Equations (2)–(6) are all extrathermodynamic.\textsuperscript{[5,37]} The choice of $n$-octanol proved to be an ideal one because, being similar to biological membranes (a polar head plus a nonpolar tail), it dissolves most druglike substances (unlike alkanes, lower alcohols, or water). In addition, although it is practically insoluble in water, octanol dissolves enough in water (2.3 M) for solutes to pass into the organic phase with their hydration shell so that they do not associate with each other. Also, octanol has a low volatility and does not absorb in the ultraviolet (UV) region. Differences between partition coefficients for aqueous solutes using $n$-hexane and octanol as organic solvents may serve as quantitative measures for the hydration/dehydration properties of molecules or substituents. Such hydrophobic interactions are responsible for micelle formation and are important for biomolecules such as proteins, or for receptor–agonist (pharmacophore) interactions.

Partition coefficients ($\log P$) may be obtained experimentally either by the “shake flask” method, or more conveniently by high-performance liquid chromatography (HPLC) measurements on reversed-phase HPLC columns and subsequent adjustment of the retention times with correction factors using standard substances.\textsuperscript{[89]} However, theoretical algorithms for computing $\log P$ values for any known or unknown molecule are available nowadays. Starting with Hopfinger and continuing with Reynolds, Klopmann, Bodor, Reddy, Katagi, and their coworkers, various quantum-chemical methods were devised.\textsuperscript{[15,31–39,49]} The algorithms most often used at present are those using either

1. a fragmental approach initiated by Rekker et al.\textsuperscript{[80–84]} who recognized that to be able to include araliphatic and aliphatic compounds, a different method had to be employed see also\textsuperscript{[85]};

2. atomic contributions, which form the basis of a computational method proposed by Ghose and Crippen (110 types of covalently bonded atom types).\textsuperscript{[96]}

Rekker’s idea was later developed further.\textsuperscript{[19,97–101]} Chou and Jurs launched a computer program called CLOGP\textsuperscript{[102,103];} other programs are also available.\textsuperscript{[104]}

### 6 DESCRIPTORS FOR ELECTRONIC, POLAR, AND STERIC FACTORS

In 1937, Hammett took the initiative in expressing quantitatively the electron-donating or electron-withdrawing effect of substituents $X$,\textsuperscript{[103,105,106]} He investigated meta- or para-X-substituted benzyl derivatives, and found that rates of reactions involving the bond-breaking of the benzyl group ($k_X$) were correlated with ionization constants $K_{a,X}$ of the benzoic acids with the same substitution pattern. Electronic effects can be expressed by the substituent constants $\sigma_{meta}$ or $\sigma_{para}$ defined as in Equation (7).

$$\sigma_X = \log K_{a,H} (\text{benzoic acid})$$
$$- \log K_{a,X} (X = \text{substituted benzoic acid})$$ (7)

The rate correlation can be expressed by Equation (8):

$$\log \left( \frac{k_X}{k_H} \right) = \rho \sigma_X$$ (8)

where $\rho$ denotes the sensitivity of the reaction to electronic effects.\textsuperscript{[103,102,103]} Since Equation (8) relates
the Brønsted relationship. Many physical properties of substituted benzene derivatives can also be correlated with Hammett’s σ parameters.

In addition to electronic effects transmitted through space or via bonds, polar interactions result either from polarization or polarizability of molecules. Polarization is a permanent effect due to electrical charges or dipole moments. As an example, the greatest difference in normal boiling points for two homologous molecules differing only by one methylene (CH₂ group) is observed for oxalonitrile (cyanogen), which boils at −22 °C, and malononitrile, which boils at 219 °C under normal pressure; the explanation lies in the fact that the former dinitrile is linear and symmetric and has no dipole moment, whereas the latter dinitrile is V-shaped and has a high dipole moment (3.58 D). Polarizability is due to the dynamic response of electrons in molecules and gives rise to dispersion forces. These forces can best be described by molar refractivities (MRs), which have an electronic component proportional to the polarizability, and are obtained as shown in Equation (9) from the refractive indices n and the molar volumes V (hence they are also related to steric parameters).

\[
MR = \frac{V(n^2 - 1)}{n^2 + 2}
\]

(9)

Ortho-Substituted benzoic acids and benzyllic derivatives do not behave normally in Hammett-type correlations because of steric effects. Taft, therefore, later introduced his steric parameter \( E_s \). Subsequent developments included the separation of inductive effects from resonance effects, the extension of the Hammet equation to polycyclic, polysubstituted, or heterocyclic aromatics, the definition of various scales for electrically charged substituents or reagents, and the use of nonaromatic scaffolds linking the substituent with the reaction center (such as four-substituted bicyclo[2.2.2]octane-carboxylic acids). \(^{109,110}\)

Other steric parameters have been introduced by Charton\(^{110}\) and by Verloop et al.\(^{111}\) Verloop et al. introduced five parameters for substituents, called STERIMOL: the first (\( L \)) indicates the length of the substituent in the direction of its attachment to the molecular scaffold; the remaining four (\( B_1 - B_4 \)) are dimensions along four directions perpendicular to the first, so that substituent flexibility can also be taken into account. The ratios \( L/B_1 \) and \( B_4/B_1 \) (the latter being the ratio of maximum to minimum width) measure the dimensions of the substituent when approximated as an ellipsoid. Usually, QSAR equations employing the STERIMOL method involve only these last three parameters. All previously mentioned steric parameters, together or separately, may enter QSAR equations in linear or quadratic polynomials.

Beginning in 1973, Simon and others introduced the concept of minimal topological difference (MTD) (an earlier version was called minimal steric difference (MSD)).\(^{6-8}\) The postulates of this approach are as follows:

1. the binding site of the biological receptor is assumed to be a cavity into which the agonist (drug or ligand molecule), in its graph-theoretical representation neglecting hydrogen atoms fits relatively tightly;
2. atoms or groups of atoms within the cavity are favored sterically, and contribute by lowering the potential energy (\( \epsilon_j = -1 \));
3. atoms or groups of atoms interfering with the cavity wall inhibit binding sterically, and increase the total energy (\( \epsilon_j = +1 \));
4. atoms or groups of atoms left outside the cavity are of no steric significance, and have no contribution to binding (\( \epsilon_j = 0 \)).

Mapping several bioactive molecules over one another in their most favorable topology or geometry gives rise to an imaginary hypermolecule. From overlapping vertices with each nonhydrogen atom \( j \) of the hypermolecule and agonist \( i \) (\( x_{ij} = 1 \) when overlapping and 0 otherwise) one can reckon the MTD\(_i\) for molecule \( i \) as shown in Equation (10) (\( S \) is the number of cavity vertices having \( \epsilon_j = -1 \) in the hypermolecule):

\[
MTD_i = -S + \sum_j \epsilon_j x_{ij}
\]

(10)

Simon’s approach was the basis for later studies by Hopfinger\(^{112}\) and Amoore.\(^{113}\)

7 THE FREE–WILSON (de novo) METHOD

Assuming that biological effects of substituents attached to a molecular scaffold are additive, Free and Wilson\(^{114}\) started with a series of compounds with the same skeleton, but with various substituents in more than one position, and with each substituent occurring more than once at each position in which it is found. Ban and Fujita reformulated Free and Wilson’s method using logarithms of biological activities, and the unsubstituted scaffold as standard.\(^{115}\) The mathematical background of this QSAR involves indicator variables (0 for the absence and 1 for the presence of a substituent at a particular position) in a matrix, plus the vector of the corresponding potency.
values, allowing a multiple regression calculation. This method is subject to the following two restrictions.

1. The minimum number of compounds in the series must be larger than the number \( \tilde{N} \) of parameters in the regression equation, i.e. (Equation 11)

\[
\tilde{N} = 1 + \sum_j (n_i - 1)
\]

where \( j \) is the number of available positions on the scaffold for substitution and \( n_i \) is the number of various substituents at position \( i \). Usually, an excess of about five compounds over \( \tilde{N} \) yields a minimum number of degrees of freedom for accurate statistical analyses.

2. No two substituents should always be present in combination; if they are, their sum can be considered as a single pseudosubstituent.

An example of antiadrenergic activities of \( N,N'\)-dimethyl-\( \alpha \)-bromophenethylamines with \( j = 2 \) positions for para (\( Y \)) and/or meta (\( X \)) substituents follows. \(^{116,117} \)

The series consisted of 22 compounds, and the \( n_i = 5 \) substituent positions were occupied by \( X/Y = \text{H, F, Cl, Br, I, or Me groups} \). The resulting QSAR equation is shown in Equation (12):

\[
\text{log} \left( \frac{1}{C} \right) = -0.30(\pm0.50)[m-F] + 0.21(\pm0.29)[m-Cl] \\
+ 0.43(\pm0.27)[m-Br] + 0.58(\pm0.50)[m-I] \\
+ 0.45(\pm0.27)[m-Me] + 0.34(\pm0.30)[p-F] \\
+ 0.77(\pm0.30)[p-Cl] + 1.02(\pm0.30)[p-Br] \\
+ 1.43(\pm0.50)[p-I] + 1.26(\pm0.33)[p-Me] \\
+ 7.82(\pm0.27)
\]

and the statistical data were \( n = 22, r = 0.969, s = 0.194, F = 17 \).

One shortcoming of the Free–Wilson model is the necessity for series that are large enough to have structural variation in at least two different positions of substitution. A large number of parameters is thus needed to describe relatively few compounds; in the above example, \( \tilde{N} = 10 \) parameters with 22 compounds leaves only \( 22 - (10 + 1) = 11 \) degrees of freedom. If a substituent occurs only once in the data set, this single-point determination will contribute with its full error to this one biological value. Most significantly, predictions for combinations of substituents that were not present in the series are limited to \( n_i' \) minus the number of degrees of freedom, i.e. \( 5^2 - 11 = 14 \) compounds in this case. No extrapolation to other types of substituents or other substituent positions is allowed.

If the numbers of substituents in positions \( a, b, c, \ldots \) are denoted by \( n_a, n_b, n_c, \ldots \), the above number of predictions should be replaced by \( (n_a + 1)(n_b + 1)(n_c + 1) \cdots - V \), where \( V \) is the total number of observed values.

A mixed approach, combining the Free–Wilson and the Hansch methods, solves some of these drawbacks. \(^{118,119} \) Although log \( P \) lipophilicities do not differentiate among stereoisomeric substituents, the Free–Wilson method can take such factors into account. The latter method was also successfully applied to peptide design. \(^{120} \)

### 8 TOPOLOGICAL INDICES AND THEIR USES IN QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIPS

The central problem in QSARs is to convert chemical structures into mathematical molecular descriptors that are relevant to the mechanism of the biological activity. Katritzky and Gordeeva. \(^{79} \) showed that for QSAR studies, TIs are among the best descriptors, but for QSPR studies they have to be complemented with other parameters (such as log \( P \), which is involved in molecular transport across biological membranes).

Recalling what was mentioned in Section 4, one may start from the simplest representation of agonist molecules (potential drugs in CALD) as molecular graphs. Their constitution is encoded in matrix form (adjacency matrix \( A \), or distance matrix \( D \)). Irrespective of the arbitrary labeling of vertices, the sums over row \( i \) or column \( i \) of these two matrices, \( v_i \) and \( d_i \), respectively, are local vertex invariants (LOVIs). The degree \( v_i \) of vertex \( i \) in organic molecules can be an integer from 1 to 4, but there is no limit for the distasum \( d_i \).

From these or related LOVIs, one can obtain global molecular descriptors, called TIs, via mathematical operations such as summation, summation of squares, summation of products over edge endpoints, etc. The simplest (first-generation) TIs are integer numbers obtained from these integer LOVIs. \(^{121,122} \) Thus, one of the first and still useful TIs was proposed by Wiener as the half-sum of distasums, and the result shown in Equation (13), is known as Wiener’s index: \(^{123} \)

\[
W = \left( \frac{\sum d_i}{2} \right)
\]

Another first-generation TI is the sum of squares of vertex degrees, \(^{124} \) shown in Equation (14).

\[
M_i = \sum v_i^2
\]
Centric indices for acyclic graphs were obtained by Balaban in 1979 by summing squares of numbers of vertices pruned stepwise from the periphery toward the graph center, which is either one vertex or a pair of adjacent vertices.\(^{[125]}\) This idea was later generalized for cyclic graphs,\(^{[126]}\) and for substituents.\(^{[127]}\)

Second-generation TIs are real numbers based on integer LOVIs. One of the most successful TIs, the integer connectivity \(\chi\), was proposed by Randic in 1975 as the sum (over all edges \(i\)–\(j\) in the graph) of the reciprocal square root of products of vertex degrees for edge endpoints (Equation 15), where the LOVIs are vertex degrees \(v_i\) and \(v_j\):\(^{[128]}\)

\[
\chi = \sum_{ij} (v_i v_j)^{-1/2} \tag{15}
\]

This idea was then generalized for longer paths than edges (which can be considered as paths of length 1 in the graph). The three carbon atoms in a propane molecule with the same number of nonhydrogen atoms attached to atom \(i\).

Kappa indexes developed by Kier are calculated relative to structures that correspond to the least-branched (linear chain) and most-branched (star graph) molecule with the same number \(A\) of nonhydrogen atoms. For paths \(L\) of length \(L\) (i.e. the count of contiguous two-bond fragments), the result is shown in Equation (17).

\[
l_K = \frac{2^{(L P_{\text{max}} \times L P_{\text{min}})}}{(L P_1)^2} \tag{17}
\]

As mentioned earlier, an edge is a path of length \(L = 1\). The nature of atoms is taken into account via a corrective factor \(\alpha\), which is derived from the covalent radius of an atom relative to that of an sp\(^3\)-hybridized carbon. For \(2\kappa_a\) as shown in Equation (18) we obtain

\[
2\kappa_a = \frac{(A + \alpha - 1)(A + \alpha - 2)^2}{(L P_1 + \alpha)^2} \tag{18}
\]

Later, Kier introduced a flexibility index,\(^{[21,133,136]}\) defined as \(\phi = (\frac{1}{\kappa_a} \times \frac{1}{\kappa_p})/A\). For a linear alkane, \(\phi = A - 1\), i.e. the count of \(C\)(sp\(^3\))-\(C\)(sp\(^3\)) bonds.

No TI proposed so far is free of degeneracy (more than one structure sharing the same value of the index), and all TIs depend both on molecular branching and molecular size. For some TIs it is possible to reconstruct the molecular constitution from the value of its TI if its degeneracy is not too high; this solution of the “inverse problem” allows one to make predictions in QSARs.\(^{[137,138]}\)

In 1982, Balaban developed the average distance connectivity index \((J)\) based on distasums,\(^{[139]}\) to reduce the degeneracy of previous indices (Equation 19).

\[
J = \left[ \frac{q}{\mu + 1} \right] \sum_{ij} (d_i d_j)^{-1/2} \tag{19}
\]

The numbers of graph edges, \(q\), and of cycles in the graph, \(\mu\), are introduced into Equation (19) to avoid the automatic increase of \(J\) with graph size and cycllicity. Indeed, for an infinite linear carbon chain, it was demonstrated that \(J = \pi = 3.14159\).\(^{[140]}\) The nature of atoms can be taken into account by means of parameters based on their relative atomic numbers, electronegativities, or covalent radii, with respect to those of carbon atoms.\(^{[141]}\)

A different approach to lowering the high degeneracy of some TIs such as the Wiener index was to make use of Shannon’s formula in information theory, which uses base-two logarithms. The first such “information theoretic indices” were proposed by Balaban and Filip,\(^{[142]}\) Bonchev,\(^{[143]}\) Trinajstic,\(^{[144]}\) and Basak et al.\(^{[145–147]}\) The former types of indices consider separately the information on each class of summands. The latter indices include all atoms (hydrogens also) in the constitutional formula, and consider the information content provided by various classes of atoms.

Third-generation TIs are based on new, real-number LOVIs and, of course, must also be real numbers. Since the set of integers, although infinite, is smaller than the set of real numbers, such TIs have less chance to degenerate than previous ones. A matrix such as \(A\) or \(D\) can be converted into a system of linear equations whose unknowns are real-number LOVIs and whose coefficients are the matrix entries supplemented by two column vectors, which can convey chemical or topological...
information; one vector replaces the zeros on the main diagonal, and the other vector provides the free terms of the equations. The result is a "triplet TI" denoted by the components of the triplet, namely, the matrix, the main diagonal vector, and the free term vector. Then the LOVs may be assembled into a TI by various operations. Thus, AZV triplet LOVIs summed over all vertices yield the "AZV topological index," which correlates well with some physical properties of alkane hydrocarbons. A stands for the adjacency matrix, Z stands for the atomic number of each nonhydrogen atom, and V is the free term vector for the vertex degree. The combinatorial nature of the triplet combinations and assembly operations affords a large variety of TIs that may be adapted to different databases.\(^{(148)}\)

Another type of LOVI results from applying information theory at the vertex level, providing an informational LOVI; then a formula similar to Randic’s index (Equation 15) assembles such LOVIs into four types of TIs denoted by the letters \(U, V, X,\) and \(Y.\)\(^{(149)}\)

The adjacency matrix \(A\) considers only nearest-neighbor interactions and is identical to the Hückel matrix in quantum chemistry; however, the LOVs derived from the distance matrix \(D\) place the largest weight on the more distant vertices. In practice, chemical interactions are strongest between adjacent atoms, but more remote atoms also exert an influence that gradually decreases with the distance, as shown by the through-bond inductive effect. Matrices modeling this feature have been devised. One is the reciprocal distance matrix whose entries are reciprocal values of topological distances; the TIs based on this matrix are called Harary indices.\(^{(150,151)}\) A different idea is to devise "regressive distances" or "regressive vertex degrees" by means of nonsymmetrical matrices whose entries in row \(i\) represent sums of topological distances or degrees, respectively, for vertices in shells around vertex \(i;\) an exponentially decreasing factor multiplies each successive shell. The results are indices that slightly change the distasum or the vertex degree, respectively, according to the molecular topology.\(^{(152,153)}\)

Newer ideas for TIs involve the adaptation of TIs to the corresponding database; one can explore the optimal molecular descriptor for that database by allowing the exponent in the formulae for \(x\) or \(J\) (Equations 15 and 19) to differ from \(-1/2,\)\(^{(154)}\) or by computing, for each database, a new type of Randic’s \(x\) index in which the adjacency matrix has, on its main diagonal, variable numbers for each type of atom instead of zeros.\(^{(155)}\)

Fourth-generation TIs are those that include information on stereoechemical features of molecules. This type of TI is now being developed, and so far there has been only limited success for diastereomers and enantiomers.\(^{(74,156–159)}\)

One should be aware that there are intercorrelations among TIs\(^{(160,161)}\); therefore, one should either eliminate collinearly correlated TIs using the statistical packages available for principal component analysis (PCA),\(^{(162)}\) or one should use Randic’s orthogonalization procedure for intercorrelated parameters.\(^{(163,164)}\)

The great advantage of TIs is their ease of calculation for any imagined structure at low “CPU (central processing unit) cost". Many QSAR studies with TIs have been published, and they can be found in reviews\(^{(165–167)}\) and in treatises on chemical graph theory.\(^{(144,168,169)}\) To facilitate the computation of TIs, commercial programs such as CODESSA, POLLY, or MOLCONN are available.\(^{(170–172)}\)

Recalling the lead optimization with 13 molecular descriptors\(^{(3)}\) described in Section 1, it is now appropriate to provide details on these descriptors for the amino acids. Four of these descriptors were TIs: three Kier–Hall indices \((\phi, \tilde{\kappa}_x,\) and \(\chi^*)\) and Balaban’s \(J\) index. Other parameters were the lipophilicity (log \(P\)) calculated according to Ghose and Crippen,\(^{(96)}\) the ellipsoidal and molar volumes, the MR, and the dipole moment. The remaining four descriptors were simple numerical data for the numbers of atoms (oxygen, nitrogen) or groups (ethyl, hydroxyl). The conclusion that one may draw from this approach confirms Katritzky’s favorable assessment of the value of TIs used together with other descriptors for QSAR studies,\(^{(79)}\) and contradicts criticisms about using TIs in QSARs.\(^{(49)}\) If TIs prove their utility for peptides whose stereochemistry is so important, then it is even more likely that they will work (together with other descriptors) for peptidomimetics or any other smaller molecules in drug design.

9 THREE-DIMENSIONAL SHAPE DESCRIPTORS

Surpassing the fourth-generation TIs, a series of shape descriptors has been reported in the literature. The rapidly increasing performance of computers now makes it possible to perform elaborate calculations for quantum-chemical parameters.\(^{(168,173)}\) The approach initiated by Mezey has allowed shape simulations to be made for various biologically important molecules such as amino acids or even macromolecular compounds.\(^{(79,174–176)}\)

The most promising of all the 3-D/QSAR methods is comparative molecular field analysis (CoMFA).\(^{(22,177–180)}\) A 3-D grid is defined so as either to (i) include the most active or the most rigid pharmacophore (ligand), or (ii) model the receptor cavity defined by its molecular docking with the potential bonding sites. Calculations are carried out at each intersection point of the
imaginary grid using force-field (molecular mechanics) methods or Gaussian approximations, Lennard-Jones potentials for noncovalent ligand–receptor interactions, and Coulomb electrostatic attractive/repulsive forces. Statistical evaluations are carried out by using partial least squares (PLS) and PCA. Cross validation is achieved by the leave-one-out procedure from the studied series, and the error is measured by a parameter named PRESS (predicted residual sum squares). The most difficult problems in CoMFA studies are connected with conformational aspects of flexible molecules and with molecular alignment.

The growing literature on CoMFA has been reviewed, and is too elaborate to be presented here in more detail. For just the brief period between 1993 and 1997, the bibliography on CoMFA has 383 references. Other descriptors that have been developed include the 3-D/WHIM (three-dimensional/weighted holistic invariant molecular) and G-WHIM (grid-weighted holistic invariant molecular) descriptors, which encompass size, shape, symmetry, and atom distribution, as well as the EVA descriptor derived from the vibrational frequencies; all of these are independent of structural alignment. Further methods related to CoMFA are HASL (hithetical active site lattice), and CoMMA (comparative molecular moment analysis), which is independent of the dilemmas raised by molecular superposition. As discussed in section 10, similarities and dissimilarities between aligned molecules can be detected by means of CoMSIA (comparative molecular similarity indices analysis).

### 10 Molecular Similarity and Dissimilarity

Molecular similarity is important when examining potential candidates for enzyme inhibitors, because inhibitors usually fit into the receptor cavity of the enzyme in the same way as the natural substrate, but their structural difference leads either to irreversible bonding or an intermediate that is no longer able to participate in subsequent reactions. A classical example is that of sulfonamides that mimic para-aminobenzoic acid (PAB) and thus act as bactericides. Among the numerous other examples are the anticancer agent 5-fluorouracil, and acyclovir or zidovudine (azidothymidine (AZT)) as anti-AIDS (acquired immune deficiency syndrome) viral agents; in these examples, the drugs mimic pyrimidine or purine bases essential for nucleic acid replication. On the other hand, molecular dissimilarity (diversity) is important when looking for lead compounds in a large database such as the Cambridge Structural Database (X-ray crystallographic data) or the National Cancer Institute Databases, because one wishes to have as much structural variation as possible.

Several books have been dedicated to this topic. TI can also be used for this purpose. Here, we discuss only the more recent developments.

For substructure searches, Burden suggested using molecular identification numbers obtained from the two lowest EVAs (and occasionally eigenvectors) of a connectivity matrix B obtained from the hydrogen-depleted graph; the diagonal element $b_{ii}$ is the atomic number of atom $i$; entries $b_{ij}$ are 0.1, 0.15, 0.2, and 0.3 for single, aromatic, double, and triple bonds, respectively, between connected atoms $i$ and $j$, and 0.01 otherwise; endpoints (vertices with degree 1) are distinguished by augmenting their $b_{jj}$ entry by 0.01. Over 20 000 structures have been successfully tested and discriminated, with the two lowest EVAs taken to 16 decimal places. A further step was undertaken by Pearlman who proposed the BCUT (Burden–Chemical Abstracts–University of Texas) approach, which consists of taking the lowest and highest EVAs, but using modified matrices: instead of atomic numbers, more relevant data for intermolecular interactions are inserted on the main diagonal, namely, atomic charges, polarizabilities, and H-bond donor and acceptor abilities (corresponding to electrostatic, dispersion forces, and hydrogen bonding, respectively). Using the program CONCORD to generate 3-D structures from 2-D (two-dimensional) structures, it is possible to introduce properly scaled information on the 3-D structure as the off-diagonal entries. With their “auto-choose” algorithm, Pearlman et al. obtained a robust program for comparing the diversities of large databases at a relatively low CPU cost.

A seductive and fairly fruitful approach to drug design was made possible by rapid advances in hardware. It involves interactive computer graphics and benefits from the fact that color on a computer screen is free, unlike color in print. This is a powerful argument in favor of electronic publishing; the future of information processing has been changed by the computer as much as by Gutenberg several centuries ago; and the “information superhighway paradox” will probably be solved in the very near future by electronic publishing.

Like 3-D physical models of molecules, computer simulations may be seen, rotated, and moved around, but, in addition, they offer many advantages:

- the geometry (interatomic distances, bond angles, torsion angles) determined by analytical methods can be accurately reflected by the model;
- the molecular energy can be calculated for any real or imagined conformation either by molecular...
mechanics (force field) calculations or by semiempirical quantum-chemical methods (ab initio methods are still too CPU-costly for all but small molecules);
• these calculations indicate which is the ground-state conformation and how much energy would be needed to change it so that it would fit the receptor cavity;
• several computer models can be superimposed to afford a 3-D image of the supermolecule and of the excluded or included volume;
• molecular docking may be simulated and dynamic approaches can be programmed.

Among the usual modes of presenting stereodrawings in color, one of the easiest to visualize is to depict the molecular contours with dots (short vectors) because one may see what lies behind the surface and one may include the molecular skeleton inside this surface; alternatively, wire, ball-and-stick, or space-filling molecular models may be imitated. Some of these models are slow to draw and therefore are not appropriate for interactive real-time graphics. Expensive computers already exist, which allow the molecular designer to view molecular models stereoscopically with polarized eyeglasses (as in 3-D movie theaters) and to manipulate them with a trackball. Chemists hope that programmers will soon be able to produce holograms, which could also be handled in print.

11 CASE STUDIES OF QUANTITATIVE STRUCTURE–ACTIVITY RELATIONSHIPS

Dihydrofolate reductase (DHFR) is an important enzyme, present in all organisms, from bacteria and protozoa to plants, animals, and humans. Folic acid (1) is a vitamin for humans, and when it is present in insufficient amounts during pregnancy, severe malformations of the central nervous system occur. It consists of three “building blocks”: pteridine, PAB, and l-glutamic acid. Bacteria (but not humans) synthesize DHFR using PAB and therefore when sulfonamides (sulfa drugs) are present, these mimic PAB and block the synthesis of (1) by acting as selective bactericides. Methotrexate (2) is a powerful inhibitor of DHFR, and acts as anticancer agent, preferentially attacking rapidly proliferating cells. The dihydro derivative of folic acid (3) is reduced by DHFR, affording tetrahydrofolic acid (4), which is able to react with formaldehyde in vitro or with serine in vivo yielding the five-membered ring intermediate (5). This compound reacts in many single carbon transfer reactions, such as the methylation of deoxyuridylate affording thymidylate (thymine is one of the four bases in DNA), and in amino acid syntheses.

Other medically useful inhibitors of DHFR, in addition to methotrexate, are the antibacterial trimethoprim (6), R = OMe, the anticoccidial diaveridine (6), R = H, employed in veterinary practice for “egg and poultry factories”, and the antimalarial pyrimethamine (7).

The amino acid homology in the primary structure of DHFR isolated from various species is high when comparing vertebrates among themselves, but low when
Comparing vertebrates to bacteria or bacteria among themselves. Binding of the substrate occurs through a combination of hydrogen bonding, electrostatic, and hydrophobic forces. The selectivity originates in subtle differences among these forces, which determine the geometry of the association between enzyme and ligand.

Equation (20) is one of the QSAR equations for the inhibition of bovine liver DHFR by trimethoprim analogs:[188,189]:

$$\log \left( \frac{1}{C} \right) = 0.62(\pm 0.13)\sigma_{\text{meta}} + 0.33(\pm 0.18)\sum \sigma + 4.99(\pm 0.07)$$  

(20)

where $n = 23$, $r = 0.931$, and $s = 0.146$.

The hydrophobicity term of one meta-substituent of the benzyl group in analogs of (6) has the largest coefficient; the $\sum \sigma$ term includes the electronic contributions of substituents in the benzylic ring. For other vertebrates, including humans, the QSAR equations are nonlinear, but not much different. On the other hand, the inhibition of Escherichia coli DHFR (a bacterial enzyme) is expressed by Equation (21)[190,191]:

$$\log \left( \frac{1}{K_i} \right) = 1.38(\pm 0.30)\text{MR}_{3,5} + 0.82(\pm 0.35)\text{MR}_4 + 5.77(\pm 0.25)$$  

(21)

where $n = 23$, $r = 0.918$, and $s = 0.250$.

Reliable and accurate apparent inhibition equilibrium constants $K_i$ express the biological activity; the $\text{MR}_{3,5}$ and $\text{MR}_4$ terms are truncated MR values of the substituents in the meta and para positions of the benzyl ring, respectively.

Equation (22) represents another equation for the same bacterial enzyme[62]:

$$\log \left( \frac{1}{IC_{50}} \right) = 0.72(\pm 0.27)\sigma_{\text{para}} + 8.85(\pm 0.16)$$  

(22)

where $n = 11$, $r = 0.892$, and $s = 0.185$.

Here the biological activity is expressed by the less accurate $IC_{50}$ (50% inhibitory concentration) values. The differences between Equations (20), (21), and (22) reflect the fact that hydrophobic interactions are more important in vertebrate DHFRs, whereas polar interactions are more important in bacterial DHFRs.[14,62]

12 Quantitative Structure–Activity Relationships in Environmental Chemistry and Toxicology

The toxicity of new chemicals is an integral part of drug design, since the therapeutic ratio contains toxicity in the denominator. In addition, the toxicity of chemicals released into the environment has become an important problem for present day civilizations. One may recall the case of organomercurials concentrated by marine organisms that led to casualties in Japan, the “Silent Spring” caused by DDT (1,1,1-trichloro-2,2-bis(p-chlorophenyl)-ethane) and emotionally described by Rachel Carson in her well-known book, or the chemical accidents in Seveso (Italy) and Bhopal (India). The polychloro-dibenzo-dioxins released in the Seveso accident, which were also present in the defoliant (Agent Orange) used in the Vietnam war, as well as methylisocyanate, which caused many fatalities in Bhopal, are extremely and acutely toxic compounds. The less acutely toxic carcinogenic polycyclic aromatic hydrocarbons (PAHs) such as benzo[ghi]pyrene and benzo[a]anthracene are, however, as dangerous when inhaled for a long time because they undergo oxidation in the liver to the corresponding epoxy-dihydroxy-tetrahydro derivatives at the “bay-region” benzenoid ring, and this ultimate carcinogen causes permanent damage to cellular DNA. Cigarette smoke as well as car exhaust gases have a significant content of such carcinogens. The Ames test is a quick means of determining mutagenic properties of chemicals, and it is inferred that there is a good correlation between mutagenic and carcinogenic activity.

The theoretical prediction of toxicities by means of QSARs is no longer wishful thinking, as stressed by Karcher and Devillers,[26] as well as by Basak.[29] Similarities between QSARs in CALD and in environmental sciences exist (Hansch approach, multivariate techniques) but the differences are more marked. In the latter sciences, the analyzed response is usually for the whole organism (although the target enzyme or organ is also relevant), the receptor and mechanism are seldom known, and the mechanism of action may be either specific or nonspecific. The aims of QSAR studies in these two fields are, of course, quite different: to find new drugs for human or veterinary use on the one hand and, on the other hand, to identify (and find ways of coping with) toxic wastes or to design pesticides.

Randic’s $T^1 \chi$ was able to model soil sorption of PAHs by means of the ratio ($K_{om}$) between organic matter sorbed by the soil and dissolved in soil water, leading to
the QSAR shown in Equation (23)\textsuperscript{28}

\[ \log K_{om} = 0.53^1 \chi + 0.43 \]  

(23)

where \( n = 72, r = 0.977, s = 0.282, F = 1478, \) and \( EV = 95.4\% \).

An early QSAR study of the toxicity (50\% lethal dose, \( LD_{50} \)) of phenols for mice is shown in Equation (24)\textsuperscript{192}:

\[ \log \left( \frac{1}{C} \right) = 0.44(\pm0.06)C \log P + 1.76(\pm0.17) \]  

(24)

where \( n = 25 \) and \( r^2 = 0.894 \).

Though the mechanism by which mice are killed is not clear, Equation (24) confirms Ferguson’s principle mentioned in Section 5.

For the toxicity of aniline derivatives on mouse embryo fibroblast cells, the QSAR shown in Equation (25) was found\textsuperscript{193}:

\[ \log \left( \frac{1}{C} \right) = -0.55(\pm0.19)\sigma^+ - 0.22(\pm0.15) \log P + 4.07(\pm0.222) \]  

(25)

where \( n = 20 \) and \( r^2 = 0.849 \).

In the last two cases, comparison with QSAR equations for organic reactions provides indirect support that free radicals may be involved in the toxic effect.

A much-studied topic deals with aquatic toxicity for vertebrates such as fish (many studies involved fathead minnows, \textit{Pimephales promelas}), single-cell eukaryotes such as \textit{Tetrahymena pyriformis}, or gram-negative prokaryotes such as \textit{Vibrio fischeri} (formerly \textit{Photobacterium phosphoreum}). One can conduct either static tests in solutions of various concentrations, or dynamic (flow) tests, for diverse time intervals. Narcosis or respiratory uncoupling caused by phenols or anilines, and acute toxicity caused by various congeneric chemicals, have been effectively modeled by QSAR equations. In most cases, a large part of the variance is explained by \( P \) values, indicating that the transport across biomembranes must be an important factor.

An example for acute toxicities (50\% lethal concentration (\( LC_{50} \)) with rainbow trout for 96-h exposure to various pesticides such as orthophosphates, carbamates, aromatic halides is shown in Equation (26)\textsuperscript{26}:

\[ \log \left( \frac{1}{C} \right) = 0.288 \log P + 1.56 \]  

(26)

where \( n = 14, r = 0.902, s = 0.195, F = 52.5, \) and \( P < 0.01\% \).

Mekenyan et al. considered a range of conformations for flexible molecules and devised QSAR equations for polychlorinated biphenyls, dibenzofurans, and dibenzo-\( p \)-dioxins in terms of quantum-chemical, topological, geometrical, and hydrophobic parameters.\textsuperscript{76,194} For multiple conformations, the COREPA (common reactivity pattern) approach can be applied not only to toxicophores but also to pharmacophores.\textsuperscript{195,196}

Experimental data for the basic toxicity of about 1500 high-production-volume chemicals is being carried out by about 200 US chemical and oil companies at high cost; the US Environmental Protection Agency has emphasized the need for observing new protocols that spare test animals. Evidently, any theoretical method that would provide reasonable guesses for the toxicity of the many thousands of chemicals produced in smaller amounts would spare considerable funds and effort.

13 STATISTICAL DATA AND COMPUTATIONAL APPROACHES

A few relevant literature data on chemometrics and statistics are provided briefly.\textsuperscript{197} As mentioned earlier, PCA multiple regression and PLS are the methods of choice. Cluster analysis and pattern recognition techniques help in detecting similarity or diversity in databases of chemical structures. Two such techniques are the \( k \)-nearest neighbor (\( k \)-NN) method, and a class modeling technique called \textit{SIMCA} (\textit{similarity}, \textit{chemistry}, \textit{and analogy}), which places objects from a high-dimensional space into lower dimension boxes.\textsuperscript{39} The DARC-PELCO method\textsuperscript{168,169,198} originated from the idea that information is structured in successive layers around a focal point, and developed corresponding algorithms. The autocorrelation method was applied successfully by Devillers in QSAR for molecular modeling and in environmental sciences.\textsuperscript{198}

For a QSAR that varies nonlinearly with structural parameters, newer and very efficient methods are artificial neural networks\textsuperscript{199–203} and genetic algorithms,\textsuperscript{204} which can be applied either separately, or more efficiently together.

14 CONCLUSIONS

Computational chemistry has reached a level of trustworthiness by producing valuable results in medicinal chemistry. Success stories for drug design were few until 20 years ago\textsuperscript{205–207}; an early discovery based on QSARs was pralidoxime (2-pyridine-aldoxime methiodide, \( 8 \)), an acetylcholinesterase inhibitor, which removes phosphate from the serine residue of acetylcholinesterase in cases of
organophosphate or nerve gas poisoning). QSARs also contributed to the discovery of cimetidine (9), as well as its furanic analog ranitidine (10) both of which are used for treating gastric ulcers as histamine agonists for H2 receptors. Nowadays, the medicinal drugs obtained by means of QSAR, CALD, and molecular modeling studies are so numerous that even a nonexhaustive enumeration would be too long to include here. Only three newer examples of commercial drugs found with the contribution of QSAR studies will be included: the antibiotic norfloxacin (11), the antihypertensive agent losartan (12), and the antiviral drug indinavir (13) used for treating autoimmune deficiency syndrome, all benefited from the results of molecular mechanics and molecular simulation simulations based on X-ray diffractometry data.

Nowadays, every major pharmaceutical company has CALD (molecular modeling and computer-assisted ligand design) and combinatorial chemistry sections, as well as proprietary databases. The tools of the trade are

1. molecular graphics and data visualization;
2. quantum chemistry at the ab initio and semiempirical levels MNDO (modified neglect of differential overlap), AM1 (Austin Method 1), and PM3 (parameterized method 3) for obtaining atomic charges, frontier orbital energies, and super-delocalizabilities;
3. molecular mechanics based on force fields and molecular dynamics;
4. molecular modeling and conformational searching on the potential energy hypersurface;
5. molecular structure databases for 2-D and 3-D structures or substructures, and criteria for similarity or dissimilarity;
6. QSARs and QSPRs using all the available panoply of molecular descriptors, from TIs to de novo (Free–Wilson) and Hansch's lipophilicity approaches, alternating computational and experimental stages for the determination of bioactivities in order to gradually improve the QSARs;
7. pharmacophore and receptor analysis using advanced statistical methods, such as artificial neural networks and genetic algorithms.

Hansch et al. recently wrote a fascinating book chapter, which should become a citation classic, since it opens many “doors of perception” and has many paragraphs and data worthy of being quoted. In brief, the authors describe how their database of about 10000 QSAR data (of which one-third are for biological/enzymatic systems and two-thirds for organic reactions) can be used to understand the chemistry of living cells, and thus to devise better drugs or pesticides. This chapter could become a gold mine for medicinal chemists and pharmacologists.

A few quotes from this last chapter (reproduced with permission of Taylor & Francis) are in order:

The advent of “sexy” 3-D pictures of ligands bound to enzymes of established structure captured researchers’ attention the way that the Lorelei of old entranced the sailors on the Rhein. Mechanism based on physical organic chemistry was forgotten…. Can SAR
(structure–activity relationship) problems be solved de novo with 3-D pictures? Our belief is that mechanistic physical organic chemistry is on the verge of an exciting new venture in helping to elucidate chemico-biological interactions that will do vastly more than simply justify its existence to make only incremental advances in our study of the chemistry of life.

The authors of this chapter indicate how to mine their rich database for relevant, meaningful, and manageable information. Then, they show by example what one can learn from such data. By grouping together QSAR equations in terms of electronic and/or lipophilicity parameters, it becomes possible to gain insight into mechanisms of enzymatic reactions. Thus, the signs and values of the slopes and intercepts in such equations are powerful indicators of the similarities and differences between complicated biochemical reactions and simple reactions that are well understood mechanistically. As biological QSARs are more difficult and expensive (and frequently less precise and with smaller numbers of data) than physical–organic QSARs, “lateral” support by the latter can add confidence in the results of the former studies. Bridges must be built between these two strictly compartmentalized areas of research. Numerous examples are presented and discussed, and several suggestions for plausible mechanisms and for promising classes of new drugs are made in this chapter.

It seems appropriate to conclude with a few other quotations from this chapter:

The rather abstract, “boring”, multivariate equations have left many who stopped to think of the enormous complexity of the problem of formulating QSAR from a set of chemicals perturbing a cell or a mouse with the feeling that they were watching a con game . . . . The 3-D graphics distracted many from trying to relate biological QSAR to the much better understood mechanistic studies from the fields of physical, organic, and biochemistry. But the enormous driving force to understand how chemicals react with the various forms of life (and its constituent parts) and the economic prospects in terms of designing the billion-dollar drug as well as understanding toxicology, have been relentless encouragement for more and more researchers to attempt what some still regard as impossible . . . . Because there are virtually an unlimited number of organic chemicals and a huge number of biological systems (DNA, enzymes, organelles, cells, and whole organisms) with which they can interact, we must develop generalizations, limited as they may be, to be used in the planning stage of synthesis of the myriad chemicals we seem to need to facilitate our existence . . . . Our present system is a small start on the problem of the design and construction of a computerized means of keeping account of what has been done and how it can be used, but we are confident that it will grow rapidly.

Robotics and Laboratory Automation in Pharmaceuticals Analysis

Nigel North
SmithKline Beecham Pharmaceuticals, Harlow, UK

Laboratory robotics is being increasingly applied in pharmaceutical development to help meet the needs of increasing productivity, decreasing drug development time and reducing costs. A robot can be defined as a device that can perform a variable but programmed series of physical manipulations including moving objects, sample identification, weighing, extraction, filtration and dilution. Robots can be classified according to the type of movement the robotic arm can perform. Three of the most common geometries for laboratory robots are: Cartesian (three mutually perpendicular axes); cylindrical (parallel action arm pivoted about a central point); and anthropomorphic (multijointed, human-like configuration). Each has been used in the pharmaceutical industry with varying degrees of success. Cylindrical and anthropomorphic robots generally provide more flexible “human-like” automation that includes transfer, weighing, extraction and filtration of samples.

In a typical analysis, four major steps are performed: sampling; sample preparation; sample measurement; and data collection/analysis/reduction to provide a report for the customer. Most laboratory robotic systems are employed to automate the sample preparation stage which is normally the most labor-intensive step of the analysis process. Automation has been applied in pharmaceutical analysis in a number of areas: raw materials release; in-process testing; release of finished products; and stability testing of the dosage form. In pharmaceutical analysis the assay, content uniformity and dissolution tests are the most common methods that use automation. Developing an automated assay or content uniformity method for a dosage form requires several aspects to be investigated before validation of the procedure can proceed, including: extraction; filter; carry-over studies; and stability of solution.

Validation can be defined as establishing documented evidence which provides a high degree of assurance that a specific process will generate a product, in our case an automated method, that will meet predetermined specifications and quality attributes. Qualification is part of validation and has been defined for installation, operation and running of the system under workload for a specific application. In the pharmaceutical industry the “4Qs” model is generally used to qualify the unit. Validation of manual analytical methods is well understood but documented in a number of guidelines in slightly different ways. It has been only recently that single documents (International Conference on Harmonisation) have emerged that describe the terminology and methodology for method validation. For robotic methods, equivalency between the manual and automated procedure is an important extra validation test that is often performed since it is unusual not to have a manual already in use. This test may not be relevant if accuracy has been also demonstrated for the automated method. For successful transfer of automated methods, the robotic systems used in research and development (R&D) should mirror those used at the commercial production site. The automated equipment must be rugged and easy to use for the production quality control (QC) laboratory to invest in the technology. Complex robotic systems that need specialist, dedicated staff, have not been generally successful in the QC laboratory.

Robotic systems are a high capital cost and this is often justified by increasing throughput since automatic systems can operate 24 h a day and over weekends unattended, thereby also reducing the cost per analysis. During the 1990s, drug development times have significantly reduced, which has required more responsive “just-in-time analysis” and this has been an integral part of cost reduction for the release of raw materials and commercial products. Automated systems also enable scientists to use their time more productively by spending time on evaluating data and on more innovative tasks rather than performing routine repetitive operations.

Although the application of laboratory robotics is increasing, limitations including high capital cost, relative complexity of operation and poor connectivity between the robot and laboratory information management systems, are hindering its implementation.
1 INTRODUCTION

Laboratory robotics is being increasingly applied in pharmaceutical development to help meet the needs of increasing productivity, decreasing drug development time and reducing costs. A robot can be defined as a device that can perform a variable but programmed series of physical manipulations,\(^1\) including moving objects, sample identification, weighing, extraction, filtration and dilution. Robots can be classified according to the type of movement the robotic arm can perform,\(^2\)

Three of the most common geometry’s for laboratory robots are: Cartesian (three mutually perpendicular axes); cylindrical (parallel action arm pivoted about a central point); and anthropomorphic (multijointed, human-like configuration). Each has been used in the pharmaceutical industry with varying degrees of success. The PAL system manufactured by CTC Analytics and shown in Figure 1 is an example of a Cartesian robot that performs dedicated relatively simple tasks such as sample dilution, mixing and filling a loop of an autoinjector with a fixed volume of solution for sample analysis. Cylindrical and anthropomorphic robots generally provide more flexible “human-like” automation that includes transfer, weighing, extraction and filtration of samples.

In a typical analysis four major steps are performed: sampling; sample preparation; sample measurement; and data collection/analysis/reduction to provide a report for the customer. Most laboratory robotic systems are employed to automate the sample preparation stage which is normally the most labor-intensive step of the analysis process. The results of one survey\(^3\) (Figure 2) indicated that about 60% of the analysis time is spent on sample preparation.

![Figure 1](image1.png)  
Figure 1 Photograph of a CTC Analytics PAL system. (Reproduced by permission of CTC Analytics AG.)

![Figure 2](image2.png)  
Figure 2 Breakdown of time spent on key steps in sample analysis process.

Automatic analyses often involve similar steps to the manual procedures but robots have an important advantage of performing these repetitive tasks accurately and precisely for long periods of time without the need for breaks. A key benefit is higher productivity,\(^4\) improved quality in terms of increased accuracy and precision of the data generated. Furthermore, automation also frees up analysts’ time for important activities such as data interpretation and more innovative tasks. Unattended analysis also reduces the exposure of the scientists to hazardous chemicals.

Although the application of laboratory robotics is increasing, limitations including high capital cost, relative complexity of operation and poor connectivity between the robot and laboratory information management systems, are hindering its implementation.

2 HISTORY

Considerable effort has been devoted over the past decades to increasing the analysis speed and as well as to improving data handling and report generating software. In contrast, automation of sample preparation has lagged behind in its development. Early examples of laboratory automation include continuous flow analyzers,\(^5\) flow injection analysis,\(^6\) and automatic titrators. With the development of inexpensive microelectronics and microcomputers, it is possible to build flexible and more...
sophisticated automated systems. These developments have led to programmable laboratory robots that perform a series of physical manipulations using some form of mechanical arm. The deployment of these devices has had a major impact on how routine laboratory tasks are performed. A diagram illustrating the evolution of automation is shown in Figure 3.

The first robotic instruments were introduced into the pharmaceutical laboratory in the early 1980s. The Zymate cylindrical robot (Figure 4) typified these systems. This robot is a modular system that uses its own programming language, scheduler and a range of accessories to automate a wide range of pharmaceutical analytical procedures including dissolution testing and tablet processing. At that time the main competitor was Perkin-Elmer’s MasterLab which employed a Mitsubishi robot, an electronics module and associated communications interfaces that enabled the system to be controlled by a high-level menu-driven programming language. This robot used anthropomorphic arm geometry with five axes of motion. During the last 10 years many other manufacturers including CRS Robots, Sands Technology, Source for Automation, Novi and Hewlett-Packard ORCA (Optimized Robot for Chemical Analysis), to name but a few, have developed laboratory robotic systems. Although these robots are laboratory based they are relatively large systems that require their own specially designed bench area and dedicated scientists to develop and maintain the equipment. To overcome these disadvantages and to enhance reliability, smaller, more dedicated systems have now been developed that are simpler robotically and are controlled by easy-to-use menu-driven programs. An example of this smaller, bench-sized robot is Zymark’s Benchmate Tablet Processing Workstation. There is now also a trend towards automation that does not use a robotic arm but instead employs dedicated accessories to perform tasks like dissolution testing. A good example of this type of automation is Source for Automation’s Automated Dissolution Module. This equipment has the added advantage of being scalable such that single or multiple dissolution units can be linked and controlled by one computer. These smaller automation systems are also more amenable to operating at-line in the production area and this, combined with the recent development of rapid non-invasive methods of analysis such as near infrared, provides the capability of generating analytical results within the manufacturing process.

3 PHARMACEUTICAL APPLICATIONS

Laboratory automation has been applied in pharmaceutical analysis in a number of areas. A summary of the basic steps in the production of a dosage form is given in Figure 5. The individual components that are used to formulate the dosage form need to be tested against a specification before the material can be released for the manufacture of a dosage form. The excipients
(nonactive ingredients) that give the formulation its fundamental properties, and the drug, must be tested against predefined specifications. Most excipients used have monographs in the United States or European pharmacopeias and involved traditional wet chemical methods. A comprehensive review of the application of flow injection analysis to automating wet chemical methods has published by Betteridge.[7]

The heavy metals test, which is a fundamental test for many materials, has been automated using flow injection analysis.[8]

A key element of building quality into the manufacturing of a product is being able to obtain information on the state of the process while it is running. During the 1990s this has started to be addressed in the pharmaceutical industry. Rapid, rugged, reliable and ideally noninvasive analytical techniques are required to provide this information. Conventional laboratory robots have been developed to analyze powders,[9] using high-performance liquid chromatography (HPLC), from blending operations in solid dosage form manufacture.[10] Automation using noninvasive methods such as near infrared has been successfully developed by Sekulic et al.[11] to provide in-process control information. A comprehensive review of the application of near infrared to pharmaceutical analysis has been performed by Blanco et al.[12]

Following the manufacture of a drug product there is a need to ensure the equipment used is clean before the next manufacture can commence. Scypinski et al.[13] automated the analysis of cleaning samples employing the Zymark Benchmate workstation.

Drug products are released by checking the batch against a predefined specification. The most common specification tests include determination of the assay, degradation products, content uniformity and dissolution of the drug product. Content uniformity is a high-volume repetitive test in which the sample preparation has been automated using the Zymate Tablet Processing Workstation by Barrett,[14] Lagade et al.[15] and Sadlowski et al.[16] More recently, Stanley and Park[17] compared the Zymark Tablet Processing Workstation II and the Waters Tablet Processing System robots using content uniformity determinations. Drug content and degradation product determinations have also been automated by Stanley.[18]

Metered dose inhaler (MDI) product analysis is highly labor intensive. Robotic systems have been developed by Monk[19] to provide a repeatable method of handling and firing the MDI product into a collection apparatus, measuring weight loss and dosage content determination. The Anderson impactor is well established for measuring particle size in MDIs and a robot to automate this process is shown in Figure 6.

There has been an increased demand for dissolution testing for solid oral dosage forms. One of the first totally automated dissolution methods was developed by Kostek et al.[20] in which the robotic dissolution system was coupled with an ultraviolet/visible (UV/VIS) spectrophotometer equipped with an on-line flow cell for real-time collecting of samples and the immediate acquisition of data. With complex matrices of drug products, some automated methods needed to have samples collected off-line for analysis.[21] Rios et al.[22] used flow injection analysis and Kostek et al.[23] used real-time HPLC analysis. With the development of fiber optics Kostek et al.[24] have applied the technology to enable the UV/VIS analysis to be performed in situ. Doddapaneni et al.[25] proposed an alternative approach for dissolution testing of nonroutine formulation development samples by employing a segmented strategy using an automated dissolution system.
linked to several fraction collectors/dilutor dispensers with an off-line UV/VIS spectrophotometer. Stability testing of finished product forms a major part of the workload in a pharmaceutical development laboratory and this is likely to increase with globalization in the pharmaceutical industry.\(^{(26)}\)

### 4 SYSTEM DEVELOPMENT AND INSTRUMENT QUALIFICATION

Robotic systems produced in the early 1990s were flexible and could be configured to perform a variety of sample preparation tasks. These instruments were developed in a time when validation requirements for computerized equipment were less stringent. As a consequence the effort and time to implement these systems was significantly less than that required now as we move into the next millennium. Manufacturers have responded by producing smaller, more dedicated automated systems that are easier to validate and use. An example is the evolution from the Zymate robot to Benchmate-type systems by Zymark Corporation.

Equipment vendors and users have worked together to share the task of equipment qualification and validation. Validation can be defined as establishing documented evidence which provides a high degree of assurance that a specific process will generate a product, in our case an automated method, that will meet predetermined specifications and quality attributes. Qualification is part of validation and has been defined by the US Pharmaceutical Manufacturers' Association Computer System Validation Committee for installation, operation and running of the system under workload for a specific application. In the pharmaceutical industry the “4Qs” model is generally used to qualify the unit and this is outlined in Figure 7.

The Pharmaceutical Analytical Sciences Group in the UK has developed guidelines\(^{(27)}\) on the requirements for the qualification of analytical equipment. Design qualification is meant to ensure that the equipment meets the purchaser’s specification and conforms to a recognized quality standard (e.g. ISO Standard 9001). The vendor should also allow the purchaser access to the software source code and validation documentation. Under design qualification a system of change control for system upgrades also needs to be in place. Protocols should also be provided by the manufacturer for the installation, operational and performance qualification stages. Installation qualification is designed to ensure the automated system that you receive is what you ordered. The environmental conditions for the location of the robot should also be checked to make sure they are appropriate. The equipment is assembled, generally by the vendor, and the system switched on. Individual units of the robot, for example balances, homogenizers, diluters and filtration devices, are checked against the manufacturer’s specifications at the operational qualification stage. Calibration checks (e.g. for balances) should be made using traceable standards. Finally, the performance qualification involves checking that all the units that make up the robot function correctly as a complete system. A typical method is run at this point to facilitate this performance check.

Software provided with the automated system should be developed using a life cycle management approach and according to a quality standard (e.g. ISO Standard 9003). The vendor should also provide certified evidence that the software has been validated (e.g. TickIT\(^{(28)}\)).

Although a lot of effort is required to validate an automated system in the highly regulated environment of the pharmaceutical industry, for the most part, this makes good business sense and helps ensure complex automated equipment operates in the way in which it was intended.

### 5 METHOD DEVELOPMENT

In pharmaceutical analysis the assay, content uniformity and dissolution tests are the most common methods that use automation. Developing an automated assay or content uniformity method for a dosage form requires several aspects to be investigated before validation of the procedure can proceed.\(^{(29)}\) The efficiency of the extraction step with respect to composition and pH of the extraction solvent together with, if used, the homogenization conditions of speed and time need to be studied. To optimize these factors efficiently, an experimental design (Figure 8) can be used to map the response surface of the extraction profile.

Suitable studies should also be conducted on the filter membrane to ensure significant quantities of drug are not retained and demonstrate that extractables from the filter do not interfere with the assay. The capacity of the filter to retain the filtrate without blocking is also important to enable the robotic system to work reliably. Automated sample preparation systems typically dispense solvents and perform dilutions gravimetrically.
Consequently, the density of each sample solution that is manipulated gravimetrically is needed to ensure volumetric requirements of the manual method are met. A robotic method usually performs analysis serially using common components such as extraction vessels and tubing. Carry-over of drug from one sample to the next must, therefore, be investigated typically by employing a sample containing no drug (blank). If a homogenizer is used to grind and extract a dosage form, the volume of solvent retained by the homogenizer probe should be determined to see if this is significant. A robotic system comprises many components that come into contact with the drug and extraction solvent, consequently checks need to be carried out to ensure extractables are not leached from the equipment and significant amounts of drug are not absorbed by the system (e.g. tubing). Stability of solution must also be investigated to ensure that not only is there satisfactory chemical stability but also there is acceptable physical stability in terms of evaporation of the sample and standard solution.

**6 METHOD VALIDATION**

Method validation should only occur after the method has been developed and optimized. It provides an assurance of the reliability during normal use and it can be described as the means of providing documented evidence that the method performs in the manner in which it was intended. Validation of manual analytical methods in the pharmaceutical industry is well understood but documented in a number of guidelines in slightly different ways. It has been only recently that single documents have emerged that describe the terminology and methodology for method validation. The parameters investigated, together with their definitions, are summarized below.

1. **Accuracy** – closeness of agreement between the true or reference value and the value found.
2. **Precision** – closeness of agreement between a series of measurements obtained from multiple samplings of the same homogeneous sample.
   - (a) **Repeatability** – precision under the same operating conditions over a short interval of time.
   - (b) **Intermediate precision** – precision within laboratories: different days, analysts and equipment.
   - (c) **Reproducibility** – precision between laboratories
3. **Linearity** – ability (within a given range) to obtain test results which are directly proportional to the concentration (amount) of analyte in the sample.
4. **Range** – interval between the upper and lower concentration (amounts) of analyte for which the method has suitable precision, accuracy and linearity.
5. **Specificity** – ability to assess unequivocally the analyte in the presence of components of the matrix.
6. **Quantitation limit** – lowest amount of analyte in a sample that can be quantitatively determined with suitable precision and accuracy.
7. **Detection limit** – lowest amount of analyte in a sample that can be detected but not necessarily quantitated as an exact value.
8. **Robustness** – capacity of a method to remain unaffected by small, but deliberate, changes in method parameters. Provides an indication of the method’s reliability during normal usage.

It has been recognized that not all the parameters described above are tested for each type of analytical method. The type of method and its intended use dictate which tests should be investigated. The scheme recommended by the *United States Pharmacopeia* for assay validation is shown in Table 1.

For robotic methods equivalency between the manual and automated procedure is an important extra validation test that is often performed since it is unusual not to have a manual procedure already in use. This test may not be relevant if accuracy has also been demonstrated for the automated method. In addition, the test for intermediate precision for an automated method may not be appropriate to investigate since a robot should not be affected by analyst-to-analyst or day-to-day variability.

The validation parameters above, combined with the data generated during method development, provide...
the necessary assurance that the method will perform satisfactorily when used by trained analysts.

7 TECHNOLOGY TRANSFER

Technology transfer from R&D to a commercial site is a key step in the pharmaceutical development process. The technology involved is not only the manufacturing process for the dosage form but also the associated analytical methods to control the quality of the product. These methods include assay, content uniformity of individual dosage units, degradation profile for the drug and dissolution methods. In the pharmaceutical industry validated methods must be transferred. The transfer process for analytical methods can range from repeating some of the validation tests, for example, linearity, accuracy and precision, to just repeating the analysis of several lots of well-characterized batches of drug product. If an automated method is available then there is usually an associated manual method. In this case there are a number of options for technology transfer and these include transfer of both the manual and automated method or just the latter.

For successful implementation of automated methods, the robotic systems used in R&D should mirror those used at the commercial production site. The automated equipment must be rugged and easy to use for the production QC laboratory to invest in the technology. Complex robotic systems that need specialist, dedicated staff have not generally been successful in the QC laboratory. For manual methods, the transfer tests not only the methodology but also the analysts that use the method. However, when transferring an automated method between robots of the same type, less validation may be required, provided that the equipment has been qualified. If there is confidence that the two robots are validated then just an electronic transfer of the method may be possible, which represents a considerable reduction of effort. Typically, repeat analysis of at least one batch of each strength of drug product is carried out on both automated systems. The data can be compared statistically; however, this can result in false conclusions particularly when the two data sets have high precision. This scenario can lead to statistical differences that are not analytically significant. The acceptance criteria for comparison of methods should, therefore, include an absolute difference (%) between the means of the two sets of results. Successful technology transfer hinges on good communication between the analyst(s) that developed the method and the laboratory that receives the procedure.

8 BUSINESS BENEFITS

A key goal for pharmaceutical businesses during the 1990s has been reducing the time to develop a product and get it to market. This benefit also means that the time it takes to find the compounds that will not be commercialized is decreased. From a business viewpoint this is equally important in that the time and money can be re-allocated to developing more new chemical entities.

The increasing cost of drug development and loss of sales that can occur if the drug is delayed, by as little as a day, is very significant for a billion-dollar-a-year product. Automation is playing an important role in helping to reduce the time to market and can be justified in many ways. Robotic systems usually are a high capital cost and this is often justified by increasing throughput, since automatic systems can operate 24 h a day and over weekends unattended, thereby also reducing the cost per analysis. During the 1990s drug development times have significantly reduced, which has required more responsive “just-in-time” analysis and this has been an integral part of cost reduction for the release of raw materials and commercial products. Robots perform operations highly reproducibly without getting tired, which should improve the quality of the data. Automated systems also enable scientists to use their time more productively by spending time on evaluating data and on more innovative tasks, rather than performing routine repetitive operations. Robotic systems also have the capability of storing an audit record of manipulations performed by the system, so if an unexpected result occurs when the instrument is working unattended, it

should be possible to find out when and what happened. This provides a high level of regulatory compliance. When analyzing hazardous materials, automated systems reduce the exposure of the operator to these substances. Robotic systems can also effectively smooth out peaks and troughs in work loads that without automation could result in staff working longer hours, introducing shift work or contracting out the extra samples. These benefits more than offset the initial capital cost of the robot, and return on investment is typically less than 2 years for most applications.

ACKNOWLEDGMENTS

I would like to thank Chris Banton, Les Brockhurst, John Gostick and John Stanley, who have worked with me over several years, for their enthusiasm and support in implementing automated methods.

Solid-phase extraction (SPE) using small cartridges filled with sorbents of a small particle size has rapidly established itself as an important sample clean-up technique. It has prospered at the expense of liquid–liquid extraction (LLE) which is considered labor intensive and frequently plagued by problems, such as emulsion formation and use of large volumes of hazardous solvents. A remarkable characteristic of SPE is its easy adaptation to on-line mode by column switching techniques; switching can be effected manually or by automated controllers.

The same analyte/sorbent interactions that are exploited in liquid chromatography (LC) are of use in SPE, but particle sizes employed are greater. Chemically bonded silica (SI), usually with C18 and C8 organic groups, is by far the most commonly used material. At present, cross-linked polystyrene and other polymeric resins and mixed-mode SPE sorbents are finding increasing use. A guide to improve sample clean-up procedure can be established.

There are different approaches to automation for both off-line and on-line SPE, which involve different levels of apparatus cost. SPE is generally easier and cheaper than LLE. The precision obtained is similar for both techniques, while the recoveries obtained by SPE are generally better than those obtained by LLE.

Enrichment and derivatization can also be carried out by use of sorbents as supports.

1 INTRODUCTION

In order to understand the place of SPE or other sample clean-up procedures in the pharmaceutical field, the drug evolution cycle should be considered. This can be divided into different steps: discovery; chemical process development; metabolism, bioavailability and pharmacokinetics; formulation studies; stability studies; toxicology and safety testing; commercial production and marketing. This cycle gives different kinds of samples that may need a pretreatment prior to their measurement. These pharmaceutical samples are bulk-drug, preformulations, formulations and biological samples. The last samples are also connected with topics such as therapeutic drug monitoring and toxicological analysis developed in many cases in the pharmaceutical field.

Nonvolatile species can be removed from either solid or liquid matrices by a number of techniques which range from distillation to dialysis, LLE, and SPE, including both ion exchange and sorption. The traditional LLE method as a sample clean-up procedure for pharmaceutical samples, has been superseded by SPE. This approach with porous solid particles (Rohm and Haas Amberlite XAD™ resins) goes back to the early 1970s. Practical use of this method was undoubtedly hindered by the necessity of grinding, sizing and purifying the early XAD™ resins. Now, with the ready availability of pure bonded-phase SI particles and, more recently, of pure polymeric resins of appropriate particle size, SPE is becoming the preferred method for isolation of organic components from predominantly aqueous samples.

Disposable cartridges filled with sorbents of a small particle size are employed, and the sample and the different mobile phases are flushed with a syringe as a low-pressure pump. The clean-up principles are similar to other open-column techniques. This method is quick and simple to operate, most sample handling losses are avoided and it is easily automated and coupled to LC. LC has probably emerged as the method of choice in the pharmaceutical
field. Gas chromatography (GC) has gained more prominence for drug screening and coupled with mass spectrometry (MS) for confirmation analysis too.

In recent years, an increasing number of LC methods incorporating on-line sample clean-up by SPE on disposable precolumns by use of column switching have been developed. Switching devices permit the off-line multistep methods to be transformed into single-step procedures by the on-line purification of the sample. The on-line coupling of SPE and capillary GC still poses a number of problems.\(^{(4)}\)

A topic close to pharmaceutical analysis is residue analysis, as the determination of antibiotic residues in food products of animal origin. SPE on disposable cartridges or precolumns has also been proposed as a substitute for or combined with LLE\(^{(5)}\) in this field.

In systematic toxicological analysis the substances present are not known at the start of the analysis. In such an undirected search the extraction procedure must be a general procedure where a compromise must be reached in that the substances of interest are isolated at a yield as high as possible and the interfering substances from the biological material are removed.\(^{(6)}\) For a long time the traditional sample work-up technique in analytical toxicology was LLE, often combined with sample pretreatment procedures such as conjugate hydrolysis, digestion and protein removal. Although LLE proved to be suitable in a substantial number of cases, the disadvantages of this technique, for example matrix interferences, emulsion formation, use of large volumes of hazardous solvents, have troubled the analyst. The SPE approach can partially overcome the drawbacks of LLE.

In recent years the development of suitable materials for SPE and an increasing demand for on-line sample treatment procedures have provided a new impetus to extraction approaches.

## 2 BASIC THEORY

This section briefly summarizes the most used sorbents and methods in SPE. The same analyte/sorbent interactions that are exploited in high-performance liquid chromatography (HPLC) are used in SPE. Ion exchangers have been also included due to their use in sample pretreatment processes and because the process involved in the separation is a physico-chemical process, as in the sorption.

### 2.1 Sorbents and Interaction Mechanisms

The first sorbent used for SPE was XAD™ resin as mentioned above. This resin is a low-polarity styrene–divinylbenzene copolymer which possesses the macroreticular characteristics essential for high sorptive capacity. In addition to polymeric resins, the solid-phase sorbents available include common inorganic sorbents (SI, alumina, Florisil\(^{(7)}\), siloxane-bonded SI materials (octadecyl, octyl, ethyl, cyclohexyl (CH), phenyl (PH), 3-cyanopropyl (CN), diol (2OH), 3-aminopropyl (NH\(_2\)), etc.), ion-exchange macroreticular resins, and specialty products such as resin-bonded phenylboronic acid (PBA) and activated carbon. Chemically bonded SI, usually with a C\(_{18}\) or C\(_{8}\) organic group, is by far the most commonly used material for SPE. At present, cross-linked polystyrene and other porous polymeric resins\(^{(7)}\) and mixed-mode SPE sorbents\(^{(8)}\) are finding increasing use.

The packing material with particle sizes in the range of 30–60µm is sandwiched between two porous frits with a pore diameter of about 20µm in a column. The bottom end of most cartridges is terminated in a leur lok fitting. The cartridges are available in several sizes containing from 50mg to 10 g of sorbent, with the 100–500g sorbent cartridges being the most used in the pharmaceutical field. Approximate values for the capacity and bed volume of the columns are 5% sorbent mass or 0.4–0.6 mequiv mL\(^{-1}\) for ion-exchange sorbents and 120µL per 100 mg of sorbent, respectively.

A more recent approach to SPE is the use of a membrane (0.5 mm thick, 25 or 47 mm in diameter) loaded with an appropriate solid material immobilized within a stable, inert matrix of fibrillated poly(tetrafluoroethylene) (PTFE). These membranes are 90% by weight particle-loaded and 10% PTFE with very dense packing of the sorbent of a smaller average particle size (8 µm) than used in the conventional SPE cartridges. The capacity of the membranes is similar to that of the cartridges, but the small bed volume allows for reduced elution volumes, resulting in more concentrated eluates. Particle-loaded membranes are supplied in disk format for large-volume use and are contained in disposable cartridges for the small volumes appropriate for pharmaceutical analysis.

For the on-line mode, the majority of the applications use particle sizes in the 10–40µm range. The internal diameters of both the sample clean-up column and analytical column should be the same, in order to minimize extracolumn band broadening. The vast majority of studies employ an internal diameter in the 2–4.6 mm range. Short precolumns (between 5 and 10 mm) are preferable because the duration of the flushing needed to remove undesirable matrix compounds is minimized. Packed precolumns are commercially available from several manufacturers, but manual slurry or dry packing of a precolumn does not present any real problems and, in addition to rapid exchange, allows the easy screening of new packing materials.

There are three general extraction mechanisms used in SPE: polar, nonpolar and ion-exchange. The main retention mechanisms for the most used sorbents are shown in Table 1.

Although the same type of SPE material can be obtained from different manufacturers, the results using SPE material from different manufacturers, and even results obtained from different batches from the same manufacturer, may show significant differences in behavior, i.e. in particle size distribution and flow velocities.

2.2 Method Development

It is recommended to find the sorbent that will provide the best results. For that, the potential interactive properties of the isolate(s) and matrix, taking note of functional groups, should be considered (Table 1). Also other known influences that may affect the extraction negatively are important, such as protein binding, properties of the isolate(s) like stability, solubility and $pK_a$.

If the analyte(s) has nonpolar (alkyl chains, aromatic rings), polar (hydroxyls, amines, keto groups), or ionic (amines, CBAs) functional groups then these properties can be selectively employed to facilitate retention. The undesired constituents of the matrix may interfere with retention of the analytes, requiring consideration of a different mechanism.

The same operational modes as in HPLC are used in SPE. Table 1 shows the option generally chosen for each sorbent.

The sample processing involves four distinct steps. Pretreatment of the sorbent with an activating solvent (such as methanol for chemically bonded SI and porous polystyrene resins) must be carried out to obtain better surface contact and to remove impurities from the sorbent. It is returned to the ready condition by washing.
with three or four bed volumes of a solvent as similar to the sample solvent in polarity, ionic strength, and pH as possible. The sample is then sorbed onto the cartridge. The maximum volume that can be sampled depends on the breakthrough volume for the analyte(s). The cartridge is then rinsed with a weak solvent to remove undesirable matrix components. In the final step the analytes are eluted by a solvent of sufficient strength to desorb the analytes in a small volume without displacing more strongly sorbed matrix components.

The typical solvents used for nonpolar extraction are methanol, acetonitrile, ethyl acetate, chloroform, acidic methanol and hexane. Methanol, isopropanol, and acetone are used for polar extraction. Alkaline and acidic buffers and high ionic strength solutions are employed for ion-exchange extraction. Acidic buffer and acidic methanol are the solvents selected for covalent extraction.

The sample and solvents are flushed into the cartridge manually by use of a syringe, by centrifugation or in a vacuum manifold that permits the processing of between 10 and 24 columns at one time generally. SPE membranes require a filtration manifold or special apparatus for multiple extraction of several disks. For the on-line option, switching valves and pumping systems are necessary.

Different strategies exist to improve the sample clean-up by SPE, taking into consideration the sorbent used. Table 2 summarizes these strategies.

### 3 OFF-LINE VERSUS ON-LINE PROCEDURES

Off-line SPE may be converted into an on-line procedure using column switching techniques. Its use in HPLC was first reported in 1973. The term "column-switching" or "coupled column chromatography" includes, in the widest sense, all techniques by which the direction of the flow of the mobile phase is changed by valves, so the effluent from a primary column is passed to a secondary column for a defined period of time. Switching can be effected manually or by automated controllers.

Coupling LC/LC is a well-established technique for sample clean-up in the analysis of pharmaceutical samples. Its success depends on the type of sample, the precolumn, the eluent and the column-switching configuration. The only significant difference with the off-line SPE is the switching network.

In the simplest configuration, only a switching valve is required in addition to a basic chromatograph. It should be indicated that during the sampling and clean-up steps, the eluent in the analytical column is stagnant. Therefore, this configuration may lead to considerable baseline fluctuations depending on the elution conditions, which limits its applicability. More powerful systems can be achieved at a reasonable cost by using an additional pumping system. In such a way, the analytical column is equilibrated during the clean-up stage, and only the fraction of eluent containing the compounds of interest is transferred to the analytical column (Figure 1).

In spite of the level of instrumentation, different transfer modes can be used. In forward flush (also called straight flush) configurations the flow direction in the precolumn is not changed during the transfer stage, which prevents solid particles retained at the head of the precolumn from being sent to the second column. However, for samples containing compounds which are strongly retained in the precolumn, backflush configurations (in which the flow direction of the mobile phase through the precolumn is reversed for the transfer onto the secondary column) are preferable, because the

![Figure 1](https://via.placeholder.com/150)
desorption of the most retained components after every injection is easier.

In order to improve sample clean-up, several columns can be coupled easily in the on-line mode by using several switching valves. In linear coupled-column systems, the peak capacities of the individual columns are summed. A review of commonly used switching networks is given by Ramsteiner.\(^\text{10}\)

One of the most obvious trends in analytical laboratories is the growing need for automation. SPE has been traditionally performed in non- (or semi) automated mode. However, an important reason for growth is that SPE is amenable to automation, and today there are several examples of commercially available systems for automated off-line and on-line SPE.

Compared with manual SPE, automated SPE also improves the reproducibility because variations in experimental parameters are reduced or even eliminated. Another important advantage of automated SPE in pharmaceutical analysis is safety, because workers are protected from toxic substances and from samples obtained from patients with a range of diseases (HIV or hepatitis B, for instance).

There are different approaches to automation of SPE, which involve different levels of apparatus cost. These approaches can be categorized into off-line and on-line systems.\(^\text{11}\)

### 3.1 Off-line Automated Solid-phase Extraction

In off-line methods the SPE cartridges are not directly connected to instrument, normally a liquid or a gas chromatograph. Unattended sample work-up and analysis can be performed as a result.

The simplest approach to automation is based on the employment of liquid-handling devices which include SPE in their functions. These workstations usually incorporate precision pumps (which deliver measured volumes of liquid to test tubes) with multisolvant capabilities, replaceable pipettes, and random access to vessels. The system also includes a SPE rack, with the cartridges or disks, and a liquid-handling probe. The probe runs in the trays (usually x–y–z), so it can reach any of the positions: samples, tubes or SPE cartridges, manipulating the sample and providing air or nitrogen (to move liquids through the cartridges) and the extraction or washing solvents. Specially designed probes or column caps create a tight seal in the cartridges. The syringe pump delivers conditioning solvents, which are then pushed through the cartridges by means of the pressurization line. Next, the sample is added and the pressurization step is repeated. If required, one or more washing solvents are also added, and pressure is again applied. Finally, the cartridge (which is over the waste container) is moved, so the sample is eluted into a clear container for further processing. Optional equipment such as a barcode reader is also available in many commercial systems. All operations are controlled by a keypad controller or by a computer. In semiautomated systems, the extracts collected are manually injected onto the chromatograph. However, total automation is possible by connecting the workstation to the analytical column, for instance by means of a loop injector. Examples of this approach to automation are the Gilson ASPEC\(^\text{TM}\) or the Hamilton Microlab SPE systems.

A more sophisticated form of SPE automation is that using flexible or semiflexible robotic manipulation. Semi-flexible systems incorporate a robot-like device which performs only a few of the steps involved in sample preparation. Some modern chromatography autosamplers fit into this category. These devices extend the possibilities of unattended sample work-up because operations typically involved in sample conditioning (internal standard addition, dilution, digestion or derivatization) can be also performed in a fully automated way. The Prep-Station (Hewlett Packard) system is a typical example of this kind of instrument.

In flexible systems, the robot can be programmed to perform all operations involved in the sample conditioning procedure: weighting, dilution, and of course, those required in SPE. Nevertheless, robots are too expensive to be used in SPE operations. For this reason, in normal applications the robot is interfaced to a SPE work-station. The robot may move cartridges from a dispenser to racks holders, remove spent cartridges or transfer collection tubes, but rarely does the robot wait for liquids to be dispensed or for air to pass through the cartridges; instead, the SPE workstation performs these operations. Robots compatible with SPE have been commercialized by different companies such as Zymark Corporation or Hewlett Packard, among others.

### 3.2 On-line Automated Solid-phase Extraction

In on-line systems, the SPE device is inserted into the liquid or gas stream of the chromatograph, which means that it becomes part of the chromatograph. Automated sample preparation with on-line SPE is accomplished by using column-switching. When the precolumn is loaded with the sample (normally a biofluid), the analytes are selectively retained. The precolumn is then washed to remove endogenous interferents, so that they are sent to waste. The analytes are finally desorbed and transferred by means of an electronically controlled switching valve, which passes the mobile phase through the precolumn, and the drug is eluted out to the analytical LC or GC column. In such a way, off-line sample manipulation is reduced to a minimum and the entire analysis can be
easily automated. Hence, SPE/LC or SPE/GC can be considered particular forms of multidimensional LC/LC and LC/GC chromatography respectively.

The SPE/LC approach is particularly well suited for pharmaceutical analysis, as a vast majority of the samples of interest are compatible with liquid chromatographic systems (especially those operating under reversed-phase conditions). Besides the inherent advantages of automation, this methodology offers some advantages over off-line automated systems, for example, protection of light-sensitive or oxidation-sensitive analytes, because during sample processing they are kept away from light and air respectively. Moreover, implementation is relatively inexpensive compared with off-line SPE devices. In many applications, the cost is little more than a switching valve and a precolumn unit over the chromatograph needed for a manual method. However, an additional pump may sometimes be necessary for washing the precolumn. Although good stability is normally achieved for the repetitive injection of 10–100 µL of untreated samples, a clear disadvantage is that periodic regeneration or replacement of the precolumn may be needed to prevent clogging, especially when processing biofluids with a large amount of proteins (for example blood or plasma). Some commercial systems incorporate cartridge holders that can be loaded with several cartridges. The individual cartridges (which act as a precolumn) are connected to the analytical column by means of a switching arrangement. Each cartridge is periodically replaced by a fresh one, so clogging or memory effects are minimized. Alternatively, SPE in the individual cartridges is performed off-line, and then the cartridges are automatically inserted into the flow stream. Examples of this type of device are the AASP (Varian) and Prospect (Spark Holland) systems.

Whereas on-line SPE/GC is quite popular in environmental analysis, its use is not widespread in the pharmaceutical field. This can be explained by the successful performance of SPE/LC methods, and also by the inherent difficulties of coupling SPE to GC, with either solvent or thermal desorption. Moreover, in pharmaceutical analysis care must be taken to prevent water-containing eluents from being transferred to the GC part of the system. This problem may be overcome by drying the cartridge with an inner gas stream before the transfer step. Another possibility is to place a drying cartridge between the SPE precolumn and the GC system. Nevertheless, with modern equipment the introduction of up to 100 µL of solvent can be achieved.

A precolumn can also be used to couple a SPE workstation to a GC chromatograph, as illustrated in Figure 1. Larger sample volumes (up to several milliliters) can be processed in the SPE cartridges. The analytes are subsequently reconcentrated in the precolumn, which facilitates the complete transfer of the relevant fraction of solvent to the GC system. A proper selection of the precolumn packing would also improve the selectivity, for example by using a packing material with retention capabilities different to those of the SPE cartridges. If required, the precolumn can be dried before connection to the GC unit. As a result, excellent sensitivity and selectivity can be achieved. For example, the system described in Figure 2 enables the detection of some benzodiazepines at low parts per billion levels from only 1 mL of plasma. Similarly, a precolumn can be used to couple a dialyzer module to a GC chromatograph (also to a LC chromatograph). The dialysis step adds selectivity as sample macromolecules do not reach the SPE unit.

A very interesting alternative for on-line automated systems with GC and HPLC is solid-phase microextraction (SPME), because difficulties derived from the injection of large volumes of solvents can be overcome. Automated SPME has been achieved by using polymer-coated fused-SI fibers. The fiber previously fixed to a microliter syringe is automatically inserted into the sample vial. The analytes diffuse and partition in the polymeric phase. Next, the fiber is removed from the vial, and the analytes are thermally desorbed, on-column, in the injector of the gas chromatograph. For HPLC an interface consisting of a six-port switching valve and a desorption camera are needed. This interface replaces the injection circuit of the liquid chromatograph.

4 PHARMACEUTICAL ANALYSIS

4.1 Quality Control

The control of pharmaceutical quality is one of the primary objectives of drug manufacturers. Quality control (QC) has been defined as actions such as testing, monitoring and inspecting taken to detect and control defects. The control of drug substances and drug product quality involves developing sets of tests and specifications for raw materials, intermediates of interest and final products, performing the tests on the subject material, compiling the results and submitting them to regulatory authorities on a regular basis. From the synthesis of a drug onwards, its identity, strength, purity and quality are continuously assessed and monitored.

The British and USA pharmacopoeias recommend microbial assay, ultraviolet (UV) spectrophotometric and HPLC methods for the determination of pharmaceutical preparations. HPLC is currently probably the most popular for impurity and dissolution testing and formulation determination. However, very few publications exist on QC applications of LC other than several examples that
Figure 2 Set-up for on-line SPC/GC (a), and the chromatograms obtained from 1 mL of plasma spiked with 100 ng mL$^{-1}$ of trazodone (T) (b) and blank plasma (c). (Reproduced by permission of Vieweg Publishing from A.J.H. Louter, R.A.C.A. van der Wagt, U.A.Th. Brinkman, *Chromatographia*, 40, 500–506 (1995).) V1, V2 and V3 are switching valves; SVE, solvent vapor exit; FID, flame ionization detector.
In the development of new drugs, the determination of the purity is important in order to establish the acceptability of batches for safety assessment and clinical trials. In general, process impurities include trace substances resulting from the drug substance synthesis, and trace side-reaction products or contaminants not removed by the isolation and purification scheme. Regulatory authorities set various levels for individual and total impurities in both drug substance and drug product that must be reported and investigated. Ideally, the total amount of impurity, as well as the quantity of each individual impurity, should be monitored in the bulk drug. Prabhu et al.\textsuperscript{13} described the isolation and concentration of impurities in 3-[2-(2-benzoxazolyl)ethyl]-5-ethyl-6-methyl-2(1H)-pyridone (L-696229) using sequential preparative HPLC, SPE, and LLE. Three SPE cartridges connected in series were used.

An example of the use of SFE in studies related to dissolution testing can be found in Kenney et al.\textsuperscript{14} The antiarrhythmic drug L-768673 in pharmaceutical preparations was retained on a C\textsubscript{18} SPE column and was analysed by HPLC and UV detection at 245 nm.

We have proposed spectrophotometric procedures that integrate sample clean-up and derivatization in the same process by using C\textsubscript{18} solid supports. The potential of this technique was evaluated determining the content of DL-amphetamine sulfate in centramine tablets using 1,2-naphthoquinone-4-sulfonic acid (NQS).\textsuperscript{15} This methodology has been also used for the determination of cephalaxin in capsules and oral suspension (both singly and in combination with bromhexine).\textsuperscript{16}

While development of racemic drugs is still permitted, examples are known in which enantiomeric pairs both have the same or different biological activity or in which one member is active and the opposite isomer is completely inactive. Enantiomeric purity is controlled in drug manufacture, storage and shipment for both bulk drug and product for molecular entities with chiral centers. The specific chiral LC methods have involved three general techniques, namely precolumn derivatization to yield diastereomers, mobile phases with chiral centers. The specific chiral LC methods have involved three general techniques, namely precolumn derivatization to yield diastereomers, mobile phases with chiral centers. Therefore, this technique is drastically reduced, as minimum off-line sample manipulation is involved. Thus, this technique can be very useful where a large series of samples must be processed. As a result, the precision is generally improved. Some examples of that improvement in the analytical results are given in papers about the analysis and determination of several drugs. For each analysis Table 3 also gives the separation and detection techniques employed. Several kinds of drugs have been included, such as anticonvulsants, anti-asthmatics, anti-arrhythmics, antibiotics, diuretics and illicits. Although the most used detector in HPLC is the UV/visible detector, examples of other detectors are shown in Table 3. Some reports with GC are also recommended. As an example of an analysis that needs a derivatization step, amphetamine and methamphetamine determination has been included in Table 3. SPE has been proposed for both reversed-phase HPLC and normal-phase HPLC. An overview of screening procedures using diatomaceous earth, polystyrene-divinylbenzene copolymers and mixed-mode bonded SI sorbents can be found in Franke and de Zeeuw.\textsuperscript{6}

As mentioned earlier, the use of column-switching techniques has become an area of major interest. Its application to drugs in biological matrices by HPLC methods incorporating on-line sample clean-up by SPE using column-switching has been reviewed.\textsuperscript{5} The time required for the sample clean-up process using this technique is drastically reduced, as minimum off-line sample manipulation is involved. Therefore, this technique can be very useful where a large series of samples must be processed. As a result, the precision is generally improved. Some examples of that improvement in the analytical results are given in papers about online sample clean-up with an octadecylsilica-C\textsubscript{18} SPE precolumn and using column-switching for screening of diuretics and probenecid\textsuperscript{38,39} and the determinations of acetazolamide\textsuperscript{40} and triamterene\textsuperscript{41} in urine samples using an octadecylsilica-C\textsubscript{18} SPE precolumn.

Antibiotics are used in food-producing animals not only for treatment of disease, but also to maintain health and

Mobile phase of acetonitrile–methanol–acetate buffer and detected by fluorescence.

4.2 Drug Monitoring

The analysis of drugs in a biofluid matrix by HPLC or any other separation–detection scheme is usually difficult owing to the large number of substances present in the sample and because the compounds of interest are often present at very low concentration. The most problematic fluids are those that contain a large fraction of proteins: blood, plasma, and serum. Cerebrospinal and interstitial fluids, as well as urine, are generally more compatible with LC, owing to their low protein content. Solid samples can be processed after solubilization and homogenization.

Many methods have been published for the determination of drugs in biological matrices using SFE cartridges for sample clean-up. Table 3 shows representative examples using different sorbents for screening analysis and determination of several drugs. For each analysis Table 3 also gives the separation and detection techniques employed. Several kinds of drugs have been included, such as anticonvulsants, anti-asthmatics, anti-arrhythmics, antibiotics, diuretics and illicits. Although the most used detector in HPLC is the UV/visible detector, examples of other detectors are shown in Table 3. Some reports with GC are also recommended. As an example of an analysis that needs a derivatization step, amphetamine and methamphetamine determination has been included in Table 3. SPE has been proposed for both reversed-phase HPLC and normal-phase HPLC. An overview of screening procedures using diatomaceous earth, polystyrene-divinylbenzene copolymers and mixed-mode bonded SI sorbents can be found in Franke and de Zeeuw.\textsuperscript{6}

As mentioned earlier, the use of column-switching techniques has become an area of major interest. Its application to drugs in biological samples by HPLC methods incorporating on-line sample clean-up by SPE using column-switching has been reviewed.\textsuperscript{5} The time required for the sample clean-up process using this technique is drastically reduced, as minimum off-line sample manipulation is involved. Therefore, this technique can be very useful where a large series of samples must be processed. As a result, the precision is generally improved. Some examples of that improvement in the analytical results are given in papers about online sample clean-up with an octadecylsilica-C\textsubscript{18} SPE precolumn and using column-switching for screening of diuretics and probenecid\textsuperscript{38,39} and the determinations of acetazolamide\textsuperscript{40} and triamterene\textsuperscript{41} in urine samples using an octadecylsilica-C\textsubscript{18} SPE precolumn.

promote growth. The use of unauthorized antibiotics or the failure to follow label directions for approved antibiotics could result in unsafe antibiotic residues in food products. Therefore, monitoring antibiotic residues in food forms part of a general policy to prevent unapproved uses of antibiotics. A review of the developments in LC methods of analysis for antibiotics (including aminoglycosides, chloramphenicol, sulfonamides, tetracyclines, macrolides and \( \beta \)-lactams) has been published.\(^5\) This paper also covers clean-up procedures such as SPE.

5 COMPARISON WITH LIQUID–LIQUID EXTRACTION

LLE has been the most used technique for sample clean-up, but SPE is now becoming the preferred method for this step of the analysis. This section focuses mainly on a comparison of the two methods.

5.1 Instrumentation

The equipment involved in using a sorption column for off-line processing can be very simple for manual use as described in earlier sections. For automated off-line SPE more sophisticated apparatus is required. On-line assemblies require only a switching valve for the simplest configuration, and additional pumps and valves for specific applications. In summary, SPE can work with or without expensive apparatus and the partial or total automation of the on-line mode is relatively easy.

In the simplest form of LLE a separatory funnel is needed. When the distribution constant of the solutes are very small, continuous extractors or countercurrent distribution apparatus is required. A continuous liquid–liquid extractor can be coupled to a gas or liquid chromatograph in three different ways: indirectly, by collecting the flow of the phase of interest in vials after the sample has been aspirated or injected into a flow injection manifold and subsequently injecting their contents manually into the chromatograph; on-line, via a simple turntable acting as an interface between the two continuous separation systems; and on-line, but directly, with no interface or discontinuity between the extractor and the chromatograph. Simplicity and the degree of automation of these three alternatives increase in the same order as they have been mentioned. In all cases SFE is generally easier and cheaper than LLE.

5.2 Recovery and Precision

Disadvantages of LLE are matrix interferences, emulsion formation, and the use of large volumes of hazardous solvents. SPE can overcome these drawbacks. The methods used for breaking an emulsion in LLE are generally time-consuming. The most common method is the addition of salt (e.g. NaCl) either as a solid or a saturated aqueous solution. Settling of the lower phase can be accelerated in a separatory funnel by the application of heat, as with an infrared lamp. More difficult emulsions may require high-speed centrifugation to separate two phases. Another technique is the use of low-melting-point organic solvents, such as ether, for the extraction of aqueous samples. Emulsions in this case are first separated by centrifugation, then the mixture is frozen in dry ice or liquid nitrogen. Finally, the organic phase is simply poured off leaving the frozen aqueous phase behind. Another option is to use filter papers.

Where extraction gives low recovery of the desired simple components despite optimum adjustment of solvent polarity and pH, recovery can be increased by using large volumes of solvent for the same sample quantity, and by using successive or continuous extraction. Following LLE of the sample, the solvent phase is normally filtered and may be further dried over anhydrous sodium sulfate, concentrated by evaporation and subjected to further clean-up procedures. The rate and extent of extraction may be different for a solute in a test system and in the presence of a sample matrix. Partial association of drug substances with proteins in plasma samples has been recognized.

Diuretics can provide a good example for testing the recoveries obtained for acidic, basic and neutral drugs in urine samples processed by LLE and off-line and on-line SI-based bonded-phase SPE. Table 4 shows results obtained in our research group.\(^{20,21,38,39}\) As can be seen in Table 4, the acidic diuretics present better recoveries by LLE in acidic conditions, while basic diuretics increase their recoveries in basic conditions. Neutral diuretics present similar values for both acidic and basic extractions. The urine blanks obtained by SPE in different SI-based bonded-phase cartridges are similar to those obtained by LLE in acidic conditions (Figure 3). The standard deviations obtained are similar to those obtained by LLE, but the recoveries achieved are better, although only a unique cartridge has been used for sample clean-up. C\(_{18}\) sorbent provides higher recoveries for all the analytes. The washing solvent used for clean-up of the matrix was water. The results obtained with 2 mL and 0.5 mL of water are shown in Table 4. The smaller amount of water (0.5 mL) should be only used if acetazolamide is the compound being analyzed.

The efficiency of the on-line method is similar to that found with the C\(_{18}\) cartridges (Figure 3 and Table 4). The recoveries obtained for standards and spiked urine are the same, indicating that the sample matrix does not affect the recoveries of diuretics and probenecid. The precision is excellent with coefficients of variation below 6% in spiked urine samples. Also, it is greatly improved
in comparison to LLE or SPE on disposable cartridges, as no on-line operation is involved.

Styrene-divinylbenzene (SDB) resins are especially interesting for analysing urine samples, since sulfate and glucoronide conjugates can be isolated. Extraction yields are in the order of 80%, with a precision of 7–27%, which are on average rather high. These types of compounds are not amenable for classic solvent extraction. The SDB resin is also used for isolating substances from other biological matrices such as blood, serum, bile, gastric content, and tissues.

The extraction yields of substances isolated from different biological samples may vary considerably, however. The resin has to be cleaned very carefully. Recently, new SDB-based SPE columns (e.g. Bond Elut ENV, Varian) have become available, which overcome the above drawbacks. Moreover, SDB material in extraction disks can minimize volumes of elution solvents while still allowing relatively large sample volumes; this is a main characteristic of the SDB sorbents. Screening methods for acidic, basic and neutral compounds using this type of material are not yet available.

6 OTHER APPLICATIONS OF SOLID-PHASE EXTRACTION

6.1 Concentration

In pharmaceutical testing (stability or dissolution tests, for example) high concentrations of analytes are usually involved. Consequently, dilution of the samples is often necessary prior to the actual measurement. In contrast, many other applications usually require some form of analyte enrichment: identification and/or quantification of drug impurities in pharmaceutical preparations (by-products from the synthesis or degradates); pharmacokinetic studies; therapeutic drug monitoring; and in those situations where the sample volume is restricted, particularly if the sample has to be divided between several screening tests. It should be noted that, in a majority of such cases, the analytes also require purification owing to the large number of substances present in the samples.

Analyte enrichment with SPE column or disk cartridges is based on collecting the analytes in a volume of solvent.
lower than that of the sample. Unfortunately, in this process, undesirable matrix components may also be concentrated, especially if low selective packings (such as common reversed-phase materials) are used for retention of the compounds of interest. For this reason, washing of the cartridges with an appropriate solvent or mixture of solvents is often needed to improve the selectivity.

In principle, the enrichment factor is only limited by the losses of the analytes from the cartridges due to breakthrough during both the sampling and the washing steps. Therefore, the success of the enrichment procedure depends on a variety of factors: sample volume and type; characteristics of the cartridge; nature and volume of the washing eluent; and volume of solvent used to collect the analytes.

In order to achieve maximum enrichment, a careful selection of the SPE cartridges should be made according to the basic principles indicated in previous sections. The main parameters to be considered are type of packing material, particle size and loading capacity. Cartridges packed with 100 mg of packing material are generally suitable for most applications involving the analysis of up to 1 mL of the most common biofluids. In many instances, apolar packings (C_{18} or C_{8}) provide nearly quantitative recoveries of the analytes and the required selectivity, as salts and other very polar matrix constituents are wasted out with a relatively small volume of washing solvent (normally water or a buffer). However, more selective packings (protein-coated phases or immobilized antibodies) may be required for some applications.

Figure 3 Typical chromatograms obtained at 230 nm from a urine sample by (a) acidic LLE, (b) basic LLE, (c) off-line SPE into a C_{18} column cartridge and (d) on-line SPE with column switching using a precolumn packed with a C_{18} packing.
For a given SPE cartridge, the volume of washing solvent should be as low as possible in order to prevent breakthrough. Therefore, the use of large volumes of samples may not compensate the losses of interesting compounds during the washing stage. With respect to the sample type, the most problematic fluids are those containing a high content of particulate material. In those cases, the employment of large sample volumes may be limited by the low flow rates attainable not only during the sample loading but also during the washing and desorption steps. This effect can be minimized if the samples are previously filtered or centrifuged to prevent blocking of the cartridge frits.

However, in order to achieve the maximum enrichment factor, the volume of solvent used to collect the analytes should be as low as possible. This volume is mainly determined by the amount of packing material in the cartridge, provided that a strongly eluotropic solvent is used for desorption. Cartridges containing 100–200 mg of packing permit the collection of the analyte in relatively small volumes, typically a few hundred microliters. Lower volumes lead to unsatisfactory reproducibility because, after the desorption step, small (and variable) fractions of the eluent may remain in the cartridges. As in LLE, the enrichment factor can be improved by evaporating the collected extracts to dryness, followed by redissolution. Evaporation, however, is time-consuming and may be inadequate if volatile compounds are going to be analyzed. It should be noted that, if chromatography is the final step of the analysis, the sensitivity attainable with the SPE column or with disk cartridges is limited by the fact that only a fraction of the collected extracts is finally injected into the chromatograph.

On-line SPE is an attractive alternative for enrichment of the analytes in chromatography (especially in LC). In this approach enrichment is based on retention of the analytes in a precolumn when a large volume of sample is flushed through it; the precolumn is then flushed with an appropriate solvent, and the enriched analytes are finally transferred to the analytical column.

The main problems associated with the direct injection of biofluids in chromatographic systems are precolumn clogging and irreversible adsorption of matrix constituents to the stationary phases. For these reasons, the volume of samples that can be processed with on-line SPE are significantly lower than those that can be handled with SPE cartridges. Otherwise, rapid pressure development occurs, and the performance of both the precolumn and the analytical column may seriously deteriorate after a few injections. Although special packings (such as restricted access materials) have been designed for the on-line SPE in the biomedical field, sample volumes of 50–100 µL can be adequately processed with conventional packings. Nevertheless, the sensitivity attainable with on-line SPE is similar to that of the off-line methods, as in the latter approach only a fraction of analyte is introduced in the chromatographic system. For this reason, on-line SPE is the best alternative for trace enrichment when the sample volume is restricted.

Moreover, careful selection of working conditions allows the injection of large sample volumes with suitable stability for most applications. For example, a straight-flush configuration (in which the flow direction of the mobile phase through the precolumn is not changed for the transfer onto the analytical column during the transfer step) protects the analytical column from solid particles or matrix components retained at the head of the precolumn, thus making possible the injection of relatively large volumes of biofluids. In addition, the precolumn lifetime can be extended by including a regeneration step in the final procedure. For regeneration, the precolumn is disconnected from the analytical column, and then it is flushed with a strongly eluotropic solvent. Since regeneration can be carried out during the chromatographic separation, the total analysis time is not increased. In many instances, occasional cleaning (e.g. when daily work is finished) allows the analysis of several samples with suitable stability and performance of the system for routine work. This is illustrated in Figure 4, which shows the effect of the successive injection of 250 µL of untreated plasma on back-pressure. Although back-pressure in the precolumn (packed with a 40-µm
C_{18} stationary phase) is approximately duplicated every 25 injections, the pressure at the top of the analytical column remains constant. Cleaning of the precolumn with an organic solvent (e.g. acetonitrile) every 25 injections reduces pressure and permits the system to be used for the analysis of many other samples. Under these conditions, quantification at sub parts per million levels is possible for a large number of compounds in plasma or urine.

Enrichment via a precolumn can also be used to overcome dilution, if dialysis is used to remove macromolecular constituents in biofluids (see section 3.2).

6.2 Derivatization

In pharmaceutical analysis, chemical derivatization is often needed to enhance the sensitivity and/or the selectivity of the overall analytical process, particularly when using LC. In this respect, most of the described procedures are based on precolumn solution derivatization because these reactions do not suffer from kinetic limitations and can be conducted under very flexible conditions (pH, temperature). In the analysis of biological samples, a preliminary step is analyte purification because the reagent can be reactive toward matrix constituents. In addition, derivatization generally involves extra sample handling aimed at removing unreacted reagent or to preconcentrate the derivatives. As a result, the final procedure may be very tedious and time-consuming.

Precolumn derivatization may be simplified in some instances with SPE materials. Krull et al.\(^{43}\) proposed a very interesting approach based on using solid-phase reagents for simultaneous clean-up and derivatization. The solid-phase reagent contains ionic or covalent labile tags that possess specific detector enhancement properties. The choice of the pore size of the solid support (or the percentage of cross-linking when using a polymer network) permits size exclusion, thus enabling retention of small molecules but hindering the large ones. After purification, the adsorbed analytes are made to react with the reactive part of the solid-phase material. Finally, the derivatives formed are desorbed for further analysis. This methodology has been successfully used for the derivatization of several amines with a variety of reagents in both off-line and on-line modes.

Another approach to derivatization with SPE supports is based on the successive addition of the SPE material (normally a resin) and the derivatization reagent to the samples. The derivatives are retained on the SPE material, and isolated from the matrix and from the excess of reagent by filtration. Next, the derivatives are desorbed from the resin, which is then separated by filtration. This methodology has been applied, for example, to simplify multiple derivatization required for the analysis of prostaglandins in plasma by GC.\(^{46}\)

Alternatively, derivatization can be carried out in conventional SPE cartridges or precolumns (in on-line SPE) as has been developed in our group. In the former approach, the SPE cartridge is used to selectively retain and/or preconcentrate the analytes, and then to retain the derivatives formed when an aliquot of the reagent is flushed though it. The analyte and the reagent are made to react for a given period of time. Then, the excess of reagent can be removed (if

</table>
required) by flushing the cartridge with an appropriate solvent. Finally, the derivatives are collected for further processing. The on-line methodology is based on similar principles, but the time of reaction is controlled by stopping the flow rate in the precolumn after injecting the reagent. It is important to note that, under this approach, sample clean-up, enrichment and derivatization can be performed without manual intervention. In addition, minimum instrumentation is needed over conventional equipments: an isocratic pump, a precolumn and a switching valve. This methodology has been applied to the LC determination of different types of compounds such as amino acids, amphetamines, and polyamines in plasma and urine, in combination with reagents typically used to improve UV or fluorescence detection, as can be seen in Table 5.

The successful determination of steroids in dosage forms and biological samples presents particular problems to the
analyst in view of the great number of members of this class and their varied properties. This article discusses, according to their medicinal categories, the various classes of steroids and steroid-like compounds which can be encountered by the pharmaceutical analyst, the general methods used in their determination, and the application of these methods to nine classes of steroidal substances.

1 INTRODUCTION

The successful determination of steroids in dosage forms and biological samples presents particular problems to the analyst in view of the great number of members of this class and their varied properties. The addition of any of a number of various functional groups to the generally non-polar, cyclopentanophenanthenrene nucleus yields compounds of widely different polarities, making extraction from the various matrices a uniquely difficult task. Steroids exhibit uncertain stability, especially to heat, as experienced in gas chromatography (GC), thereby frequently making derivatization necessary. The generally nonconjugated nature of the final structures has few chromophores, making detection and quantitation by ultraviolet (UV) analysis problematic. The extremely low levels found in biological samples make necessary extensive extraction and concentration before analysis. This article discusses, according to their medicinal categories, the various classes of steroids and steroid-like compounds which can be encountered by the pharmaceutical analyst, the general methods used in their determination, and the application of these methods to nine classes of steroidal substances.

2 DISCOVERY AND HISTORY

Steroids possess the skeleton of cyclopentanophenanthenrene or a similar skeleton derived by one or more bond scissions, or ring expansions or contractions. An alkyl side chain may be present at C-17, and methyl groups are often present at C-10 and C-13. The ring lettering and the numbering systems for steroids are illustrated in Figure 1, using 5a-cholestane. Steroid nomenclature derives from this compound for sterols and from three other simple steroids. These are 5a-androstane, the precursor of the androgens, which has no side chain at C-17, 5a-pregnane, the typical compound for the progestins and corticoids, which has a \(-\text{C}_2\text{H}_5\) at C-17, and 5a-estrane, which has no C-17 side chain and no C-19 methyl group.

Because of the important biological activities and wide medicinal use of steroids, the analysis of these compounds is important in both clinical biochemistry practice and industrial applications. The great diversity of steroid structures and the wide range of their physical properties present special problems for the analysis of the different classes of steroids.

3 MEDICINAL CATEGORIES

The major therapeutic classes of steroids, defined by their physiological function, are the sterols, the androgens, the estrogens, the progestins, and the corticoids (which include the glucocorticoids and the mineralocorticoids), and vitamin D. Other therapeutically important substances with steroid-like structures include bile acids, and the cardiac glycosides.

Sterols are steroids carrying a hydroxyl group at C-3 and most of the skeleton of cholestane. Additional carbon atoms may also be present in the side chain. Among the sterols, cholesterol is unique because it is the biochemical precursor of virtually all other steroid hormones. The determination of free cholesterol in human serum is of great clinical importance in the diagnosis of hepatic disease and other studies of clinical pathologies.

Androgens and anabolic agents include natural hormones and semi-synthetic analogs. Naturally occurring androgenic hormones include testosterone and its potent metabolite dihydrotestosterone. Testosterone has two important functions: androgenic and anabolic. The primary use of androgens and anabolic agents is as androgen replacement therapy in men.

The estrogenic steroids exhibit similar chemical characteristics, which include an aromatic A ring and a hydroxyl group at the C-3 position. Conjugation appears very important in estrogen transport and metabolism and primarily involves the combination of estrogen with glucuronic acid and, to a lesser degree, with sulfate. The conjugated estrogens also have physiological activity.

Estrogens are of clinical and analytical interest for many reasons. They have been widely used in birth control, the prevention and treatment of osteoporosis, the treatment of estrogen deficiency, and the treatment of advanced breast and prostate cancer.

Equine estrogens (conjugated estrogens, esterified estrogens) are largely mixtures of estrone (E1) sodium
sulfate and equilin sodium sulfate with traces of other estrogenic substances. Originally they were obtained from horses, in particular pregnant mares, but now they also are produced semisynthetically from diosgenin and other natural precursors.

The progesterones are involved in the preparation for and maintenance of pregnancy. Progestins are compounds that have biological activities similar to progesterone. This group consists of progesterone (4-pregnene-3,20-dione) and its derivatives, and 19-nortestosterone. The most common use of the progestins, as for the estrogens, is for inhibition of ovulation.

Cardiac steroids are a group of compounds that increase the contractility of the heart and can be very useful in the treatment of congestive heart failure. The most familiar of these is digoxin. Since its therapeutic index is relatively narrow and toxicity is a serious problem in therapeutic use, accurate analytical methods are essential. The cardiac steroids are involved in the preparation for and maintenance of pregnancy. Progestins are compounds that have biological activities similar to progesterone. This group consists of progesterone (4-pregnene-3,20-dione) and its derivatives, and 19-nortestosterone. The most common use of the progestins, as for the estrogens, is for inhibition of ovulation.

Cardiac steroids are a group of compounds that increase the contractility of the heart and can be very useful in the treatment of congestive heart failure. The most familiar of these is digoxin. Since its therapeutic index is relatively narrow and toxicity is a serious problem in therapeutic use, accurate analytical methods are essential. The cardiac steroids are found in a variety of plant species, Digitalis purpurea and D. lanata have been the most important overall sources of cardiac steroids.

The bile acids are anionic detergents biosynthesized from cholesterol and found in the intestinal tract and in bile. Their action is to emulsify fats, fat-soluble vitamins, and other lipids so that they may be absorbed. Almost all of the cholesterol not used for the formation of steroid hormones is converted to bile acids, which then react with glycine or taurine to form conjugates, which are secreted in the bile. In the intestine, the conjugates are converted to cholic acid, deoxycholic acid, and several other bile acids, many of which are then reabsorbed. Human bile contains five major bile acids, viz., cholic, chenodeoxycholic, deoxycholic, ursodeoxycholic, and lithocholic acid.

The vitamins D are fat-soluble seco-steroids, so called because they have undergone a fission of the B ring between carbons 9 and 10. Ergocalciferol (vit D2) is formed in plants and cholecalciferol (D3) in animals and both have identical but low activity in humans until metabolized to active forms.

4 METHODS USED IN STEROID ANALYSIS

4.1 Ultraviolet/Visible Spectroscopy

Ultraviolet/visible (UV/VIS) spectroscopy, which became available as a routine tool in the 1940s, has an important role in both quantitative and qualitative steroid analysis because of its high sensitivity and selectivity, low cost, and ease of automation. Using a scanning diode-array UV spectrophotometer as a detector following high-performance liquid chromatography (HPLC) separation broadens the applicability of both techniques.

UV/VIS spectrophotometry permits the easy characterization and quantification of those steroids containing conjugated unsaturated systems, such as ‘4-en-3-one’ type, estrogens, and trienes of the vitamin D series. Unconjugated steroids with isolated double bonds can also be analyzed using lower wavelengths. A variety of chemical derivatizations have been employed to enhance the UV method in the analysis of UV non-absorptive steroids or to increase the sensitivity and selectivity. UV analysis of steroids depends usually on the identification of the following chromophoric groups.

A set of simple rules, developed through examination of UV spectroscopic data for a wide variety of compounds, including steroids, allows the prediction of \( \lambda_{\text{max}} \) (often within 2–3 nm of the observed value) for conjugated dienes and polyenes.\(^1\) The parent diene is assigned a base absorption at 214 nm and increments are added for substituents. For example, each additional double bond results in a shift of +30 nm and a heteroatom substituent adds 5 nm. For \( \alpha,\beta \)-unsaturated ketones, the UV absorption associated with the \( \pi \rightarrow \pi^* \) transition is the most important. The rules for calculating \( \lambda_{\text{max}} \) for such systems are similar with those rules for conjugated dienes and polyenes.\(^1\)

The phenolic hydroxyl group at C-3 in the estrogens is a substituent of common interest in steroid UV analysis, owing to its effect on band maxima. For example, the UV absorption spectrum of estradiol (E2) shows a maximum at 280 nm, with strong absorption below 200 nm, which represents the main maximum of benzene. For steroids that are aromatic in both the A ring and the B ring, such as certain estrogens, the spectra are more complicated, with characteristic absorption at 280 and 342 nm, and also strong end absorption below 200 nm.

4.2 Infrared Spectroscopy

In the 1950s, infrared spectroscopy (IRS) was the only effective method for the identification and structure
elucidation of steroids. Although its importance decreased after the developments of nuclear magnetic resonance (NMR) and mass spectrometry (MS), it is still an essential tool for the rapid identification of steroids. It has rarely been used for quantitative analysis because of the low sensitivity and difficulty of sample preparation. The potassium bromide pellet method is mainly used and is generally specified in the United States Pharmacopeia (USP) 23 for the identification procedure.

Infrared (IR) spectra can provide evidence of functional groups in the sample, but can only give very limited information about the skeleton structure. In the analysis of steroids by IRS, most of the useful bands are above 1500 cm\(^{-1}\). The pattern of peaks below 1500 cm\(^{-1}\) cannot be assigned to specific vibrations, but occasionally it is characteristic of the steroid and might be useful for identification by comparing the spectrum with that of an authentic sample.

4.3 Nuclear Magnetic Resonance Spectroscopy
The major utility of NMR is to provide information about steroid structure, since it yields information about the molecular framework and functional groups, whereas IR only provides information on functional groups and UV only on conjugated systems. Another significant advantage of NMR is that it is non-destructive and samples can be recovered for further testing. More detailed information about applications of NMR in steroid analysis are available from various sources.\(^{2,3,4,5}\)

4.4 Chromatographic Methods
Although steroids can be determined by using many methods, the identification and determination of the individual steroids require an efficient separation that can be performed only by extraction and chromatography. Chromatographic methods are important tools for the separation and the determination of steroids because of their high sensitivity, selectivity, efficiency, and separation power.

4.4.1 Thin-layer Chromatography
Thin-layer chromatography (TLC) is still one of the most important tools for the rapid separation and identification of steroids because of its ease of operation, its low cost of operation, and its ability to analyze many samples. The data obtained from TLC are used for the estimation of parameters in other analysis, such as capacity factor in HPLC.

Silica gel, a polar acidic material, is the adsorptive material most usually used and it can be modified for special purposes with other substances, such as bases, buffers, and salts. Aluminum oxide, a basic material, has been used for the separation of C-19 androgens. High-performance thin-layer chromatography (HPTLC) uses microparticulate silica and can achieve increased resolution owing to the higher surface area. Reversed-phase thin-layer chromatography (RPTLC), in which the surface is made non-polar by bonding C\(_{18}\), C\(_8\), or C\(_1\) groups to the silica surface, is also available.

Aside from its relatively low resolution power compared to other chromatographic methods, one of the disadvantages of TLC is difficulty in visualization on the plate of the steroids of interest. For adsorptive steroids, UV spectroscopy can be employed. For nonadsorptive steroids, a wide variety of methods, which usually involve spraying and/or heating with some reagents, is available for visualizing the steroids of interest. Two other optical methods have been used, namely direct fluorescence detection following UV excitation, and fluorescence quenching. The latter technique involves incorporation of a fluorescent compound into the silica gel; the fluorescence of this compound is quenched in the presence of a UV absorber, and renders the compound visible. All of these visualization techniques can be divided into non-destructive and destructive methods. Since inspection of a TLC plate by eye has only a sensitivity of 1 to 10 \(\mu\)g and a reproducibility of about 20%, instrumental detection is considered important and sometimes essential for TLC.

4.4.2 Gas Chromatography
Since its introduction, GC has rapidly become a standard method in the biological and clinical analysis of steroids owing to its high sensitivity, selectivity, and separation power. In modern practice, capillary columns, usually wall-coated open tubular (WCOT) columns in which the stationary phase is coated on the inside of a column with an inside diameter of about 0.2 mm, have replaced the once widely used packed column. These capillary columns may have lengths up to 30 m, and now they provide one of the most powerful means for the separation of steroids. Megabore columns with internal diameters of 0.5–0.75 mm and greater capacity but decreased resolution are also available.

In GC, more than in HPLC and TLC, efficient separation depends mainly on the selection of an appropriate stationary phase since there is a limited choice of mobile phases. The stationary phase is a thermostable compound, which is coated on an inert support, usually diatomaceous earth, or directly on the walls of the column. Chemical bonding of the stationary phase to the support or the column wall reduces “bleed” or the slow elution of the stationary phase from the column. Chemical modification can be used to produce a variety of stationary phases with different selectivities.

In the GC of steroids, silicone oils are the most generally employed mobile phases, since they are suitable for the
separation of steroids based on their molecular weight or shapes. The carrier gas is usually nitrogen because it is cheaper, although helium is less dense than nitrogen and gives better resolution. Capillary GC separation of steroids and derivatives are best achieved by using non-polar stationary phases. Only estrogens, sterols, and bile acids require slightly more polar phases.

In order to improve the separation and/or to increase the sensitivity of detection in some cases, chemical derivatizations are frequently necessary for the GC analysis of steroids. The choice of derivatives depends on both the detection method and the chromatographic requirements. Post- and precolumn reactions may be employed. For hydroxyl groups, ethers are usually formed, most commonly trimethylsilyl (TMS) ether derivatives. Other ethers also have been used, such as dimethylethylsilyl ethers for the separation of bile acids and halogenated ethers for use with electron capture detection (ECD). The use of tertiary butyldiethoxysilylethers is very common for quantitative gas chromatography/mass spectrometry (GC/MS), because these derivatives give mass spectra without extensive fragmentation. Other derivatives such as formates and acetates have also been used. Oxo groups can be derivatized as oximes or enol-TMS ethers. For the carboxyl group, methyl esters are usually formed. The carboxyl group is frequently derivatized precolumn, usually by forming methyl ester derivatives with diazomethane.

Three kinds of detector have been used in steroid analysis. The flame ionization detector is the most commonly used, since it can give out a signal that varies linearly in response factor to most of the steroids and has a large linear dynamic range. Nitrogen–phosphorus detection (NPD), also known as thermionic ionization detection (TID), can detect nitrogen- and/or phosphorus-containing steroids or derivatives selectively. ECD is extremely useful for halogen containing compounds. However, since steroids do not usually contain nitrogen or halogen, derivatization is necessary before the use of gas chromatography/nitrogen–phosphorus detection (GC/NPD) and gas chromatography/electron capture detection (GC/ECD).

GC/ECD has been replaced by GC/MS because of the difficulty in quantification by using ECD, since it has a narrow range of linearity. When operated properly, GC/MS can be as sensitive and more selective than GC/ECD. A major advantage of GC/MS is that some of the steroids can be detected without derivatization, but its high cost limits its use in routine determinations.

4.4.3 High-performance Liquid Chromatography

HPLC has become an important tool for the separation and the determination of steroids because of its high sensitivity, selectivity, efficiency, and better chromatographic properties compared to the other methods. One of the main advantages of HPLC over other chromatographic methods is that no decomposition or rearrangement occurs during the chromatography as in GC and TLC. In addition, HPLC is a powerful tool for the separation of conjugated compounds and isomers, which are relatively difficult to separate by GC. Although derivatization procedures have been described for almost all of the steroids in HPLC, almost all of them are used for increasing detectability and have no important effect on the separation.

Usually, HPLC columns used in steroid analysis are 10–50 cm in length, 4–5 mm in internal diameter, and with 60,000–80,000 theoretical plates per meter. Microbore HPLC using columns 20–50 cm long and with internal diameters of 0.5–2 mm can provide higher sensitivity and efficiency, although it requires specialized pumping equipment and sample injectors as well as microvolume detector cells.

Both normal and reversed-phase high-performance liquid chromatography (RP-HPLC) can be used for steroid separation. In normal HPLC, high-performance silica and alumina stationary phases have been successfully used. In RP-HPLC, silica packing bonded on the surface with octadecyl or diol groups are most used. The separation depends largely on partition so that the selectivity varies with the length of the carbon chain on the column, the form of the support material, and the properties of the mobile phase.

Mobile phases consisting of only one or two solvents are those mainly used in steroid separations; however, multisolvent mobile phases may be especially useful for particular separations. A preliminary analysis by TLC can be used to test the suitability of the mobile phase chosen. Although most steroids are well separated by HPLC, the best separation of a variety of steroids has been achieved by gradient elution, which includes linear, non-linear, and stepped modes. Beside solvent constitution, the pH, as well as added ion-pair reagents and modifiers are also influential factors on the selectivity of the mobile phase. Ion-pair chromatography is preferred for the separation of steroid conjugates and bile acids. Micellar chromatography, in which some compounds, such as sodium dodecyl sulfate (SDS) are added, has been claimed to improve the separation of HPLC, especially the separation of optical, geometrical, and structural isomers. Nishi has reviewed pharmaceutical applications of micellar liquid chromatography (MLC).

UV absorptive steroids or derivatives can be detected directly by UV detection, which is the most widely used detection technique in the conventional HPLC analysis of steroids. Post- and precolumn derivatization have been used to form UV-absorbing derivatives, which may also increase the sensitivity. Since the sensitivity of HPLC with UV detection is around 1 ng per injection, UV
detectors cannot provide enough sensitivity and selectivity for many steroids, in particular the polar steroids, such as bile acids. As a consequence, laser-induced fluorescence (LIF) detection may be used\(^\text{17}\) to increase the limits of detection and quantitation. Fluorescence and electrochemical detectors have achieved determination of steroids at the picogram level. The sensitivity of detection has been extended by developments in biospecific detection principles, e.g. radioimmunoassay (RIA) coupled to HPLC.\(^\text{8–12}\) This area has been reviewed\(^\text{13,14}\)

### 4.5 Mass Spectrometry

Modern MS methods can analyze almost all steroids and steroid conjugates. MS has been used as a qualitative analysis method by comparing the observed spectrum with the spectra of known compounds, and/or by deducing the structure from the presence of characteristic fragments. MS also has been used in steroid quantification since the intensity of signals is proportional to the quantity of the compound present.

The main two roles of MS in steroid analysis are structure elucidation and quantitative analysis. The MS measurements for structure elucidation include the determination of molecular weights, the determination of elemental and isotopic compositions, and the evaluation of the fragmentation characteristics of the analytes. For molecular weight determination, it is often desirable to suppress fragmentation through the use of soft ionization, but for other structural studies the fragmentation products of the analytes provide most information. Modern MS can offer high sensitivity for the qualitative and quantitative analysis of both isolated analytes and of specific analytes in a mixture.

MS analysis involves three essential steps: ionization of the sample, resolution of the resulting ions, and detection of the ions. Sample introduction and data processing are also integral and important parts of MS. The principal techniques of ionization and sample introduction employed in MS analysis of steroids are summarized in Table 1.

Steroids can be analyzed directly by MS using a heated sample probe, which allows the insertion of the analyte directly into the vacuum and in the vicinity of the ionization chambers. However, because of the nature of most samples presented for analysis, it is usually more effective to integrate MS on-line with other techniques, which include GC, HPLC, supercritical fluid chromatography (SFC), and capillary electrophoresis (CE). In these cases, sample introduction can be performed through these instruments but usually a special interface is necessary to separate the analyte from the sample matrix.

MS methods are categorized mainly by the ionization techniques used, because the ionization step has the most important impact on the appearance of the mass spectrum and the application of MS. The methods using low internal energy, such as CI and field ionization are called ‘soft’ ionizations and give a high yield of protonated and cation-coupled molecular ions with little or no fragmentation. Other methods, in which high internal energy is transferred, such as electron impact (EI) ionization, usually cause extensive fragmentation of the sample.

Depending on the type of instrument used, the ions have kinetic energy from a few eV to as high as 10 KeV. Resolution of the ions expelled from the ion source according to their \(m/z\) ratios is accomplished by studying their flight through one or more analyzers, including momentum (magnetic sector), resonance frequency (quadrupole, ion cyclotron resonance and ion trap), kinetic energy (electric sector) and velocity (time-of-flight). The most commonly used MS ion-resolution methods for steroid analysis are the magnetic sector and quadrupole instruments. They are compatible with almost all of the ionization methods except plasma desorption ionization.

Data processing systems assure the efficient use of the enormous amount of data generated by MS and the precise control of complex instrumental parameters for various applications. The main functions of the data systems include the digitization and rapid storage of the data, mass and intensity assignments for every ion, and representation of the data in an easily comprehensible graphic or tabulated form.

Determination of the isotope composition of steroids is another important application of MS in steroid analysis.

---

and can be easily accomplished with the use of low-resolution measurements. The ion clusters observed in every steroid spectrum are due to the naturally occurring minor isotopes such as $^2\text{H}$, $^{13}\text{C}$, and $^{18}\text{O}$, etc. in which especially informative are the isotope pairs of $^{35}\text{Cl}$ and $^{37}\text{Cl}$, and $^{79}\text{Br}$ and $^{81}\text{Br}$, and the complex isotope pattern of certain metals. Because an isotope can be relatively easily measured by MS, stable-isotope labeled substances offer a convenient way to study the metabolism of steroids in humans. The $^{14}\text{C}$ radioisotope is also commonly used in drug metabolism studies at enrichment levels. For the same reason, $^2\text{H}$, $^{13}\text{C}$, and $^{18}\text{O}$ labeled steroids are extensively used in reaction and fragmentation mechanism studies and as internal standards in quantitative measurement.

4.5.1 Quantitative Determinations

Since its introduction, MS, especially when combined with GC or LC, has been one of the most useful forms of quantification available since it excels in sensitivity, accuracy, dynamic range, and specificity at trace level. As a result, MS has become the method of choice for the quantitative determination of many biologically important steroids. The various concepts of quantitative MS have been reviewed by Millard.

4.5.2 Tandem Mass Spectrometry

Tandem mass spectrometry (MS/MS) provides a method for determining the precursor ions of the fragmentation ions. MS/MS can be performed by using a triple quadrupole combination or a double-focusing sector instrument. Hybrid instruments, which couple a double focusing instrument with a quadrupole collision cell and quadrupole mass analyzer, have also been used. Since MS/MS is so highly specific, low-level constituents in biological samples or chemical mixtures can frequently be determined with little or no sample purification.

Derivatizations are occasionally employed in MS for one or more of the following purposes: to meet the requirement of sample volatility, to improve sample stability, to improve chromatographic properties, to enable functional group analysis, and to modify the fragmentation pattern.

4.5.3 Gas Chromatography/Mass Spectrometry and High-performance Liquid Chromatography/Mass Spectrometry

GC/MS is one of the most important techniques in pharmaceutical studies and in steroid analysis because the resolving power of capillary GC is combined with the high-specificity and sensitivity of MS. For instance, since isomeric steroids may be difficult to distinguish by MS but can be easily separated by GC, they can be identified by GC/MS. Similarly, the combination of HPLC with MS/MS offers special importance in the analysis of large numbers of samples in complex matrices. When coupled with GC or HPLC, the MS can be used in a selected/multiple ion monitoring mode and/or total monitoring mode. The most common and informative mode of operation is scanning the mass spectrum at frequent intervals across the full mass range. The individual spectra from each peak can be subsequently examined and used for identifying the analytes.

4.6 Immunoassay Methods

Competitive binding assays, in which the binding proteins included antibodies and specific receptors, were introduced by the early 1970s. Immunoassays have been proven to be more appropriate analytical tools for steroids in biological materials, such as serum or plasma, and alternatively urine and saliva. The current immunoassays for steroids have much improved sensitivity and precision as well as reduced cost and simplified procedures.

Although immunoassays can be highly specific and sensitive, errors may occur because both the characteristics of the antibody employed and the sample matrix can affect the assay. Cross-reactivity is always a major concern in immunoassays. For steroid analysis, cross-reactivity may come from structurally related steroids, derivatives of the analyte, or metabolites of the analyte.

Both monoclonal and polyclonal antibodies have been used in immunoassays of steroids. The main problem in the antibody production is that steroids and related compounds are too small to be immunogenic. They have to be coupled to large carrier compounds, proteins such as bovine serum albumin (BSA), to elicit the production of antibodies. Many factors of the steroid–protein conjugates may affect the antibodies produced, including the method used, the position and number of the linkage, and the steric structure of the conjugate.

Several kinds of label have been used for detection, including radioactive, enzymatic, fluorescent and chemiluminescent compounds. Radioactive labels are most commonly used, but there is an increase in the use of non-radioactive labels, mainly because these procedures are safer, cheaper, simpler, and sometimes more precise and sensitive.

Tritium has been the most widely used radiolabel in the immunoassays of steroids, although iodinated labels are also frequently used. Multiple labeling of the steroid is usually necessary in order to produce high specificity. The main advantages of iodine labels over tritium labels include higher specificity, lower cost and lower quenching.

Enzymes have been proven to be sensitive and versatile labels in the immunoassays of steroids because the endpoint signal is amplified by the enzymatic reaction.
Versatility results from the variety of enzymes and end-point reactions that can be used. The most widely used enzymes in steroid analysis are horseradish peroxidase (HRP) and alkaline phosphatase.

Fluorescence detection is generally a very sensitive method, but practically its sensitivity is restricted to a concentration range of $10^{-9}$–$10^{-12}$ mol L$^{-1}$ owing to the background signal produced by other fluorescent materials, particularly in biological samples. The fluorescent molecules that have been most commonly used in steroid analysis including fluorescein, rhodamine, umbelliferone, and rare earth chelates. The latter are especially useful because of the long half-life time and the differing fluorescent spectra of various rare earth chelates, which makes possible the simultaneous measurement of several analytes by using different chelates, such as those of europium, samarium, and terbium.

Chemiluminescence is effected by a chemical reaction, usually an irreversible oxidation reaction. This reaction may be mediated by enzymes, temperature, or electric charge applied, and they are termed, respectively, bioluminescence, thermochemiluminescence and electrochemiluminescence. Many organic compounds are luminescent upon oxidation and have been used in immunoassays as labels, including the cyclic hydrazides such as isoluminol (6-amino-2,3-dihydrophthalazine-1,4-dione) and its derivatives, aminonaphthyl hydrazides, and acridinium esters and their derivatives. Chemiluminescence has also been used in enzyme immunoassays (EIAs) as an end-point.

5 STEROLS

Because of the implications of free cholesterol in atherosclerosis, heart disease, and hepatic diseases, accurate methods for its analysis in human serum are necessary for precise clinical diagnosis. Accurate determination of cholesterol is also important in the food industry. Historically, the methods used for such analyses have been relatively simple to allow for rapid estimation, and have been based mainly on colorimetric or enzymatic reactions. Because these methods lack sensitivity and suffer from interference, they are not reliable in the analysis for cholesterol in physiological fluids other than plasma. Hence, several chromatographic methods$^{(16)}$ have been developed, including GC$^{(17,18)}$ and HPLC.$^{(19)}$

5.1 Gas Chromatography

GC has great importance in the analysis of free sterols but, because of their polarity, it is often necessary to analyze them as their derivatized forms. The shape of the sterol molecule is critical in determining the separation for sterols in GC. Planar sterols generally have longer retention times than non-planar ones on a column of given polarity. Long capillary columns have been used for separation of isomeric $C_{24}$ sterols. The great advantage of GC over other chromatographic techniques is that it is ideal for coupling with MS. The major disadvantage of GC is that many sterols are thermally unstable.

Rodriguez-Palmero$^{(20)}$ reported an accurate method for the determination of sterol content by capillary gas chromatography (CGC). The procedure includes: dichloromethane–methanol (2:1, v/v) extraction, saponification at 80°C, derivatization to form TMS ethers and GC. The method shows good accuracy, precision, and sensitivity and is suitable for the determination of sterols in food.

Garcia Regueiro$^{(21)}$ developed a reproducible procedure for the determination of eight cholesterol oxides using on-column injection and solvent venting capillary gas chromatograph. The method consists of the combined use of solid-phase fractionation and TLC. The determination of cholesterol oxide TMS derivatives was performed by using CGC. On-column CGC gave absolute area relative standard deviation (RSD) values of 3% to 6%.

5.2 High-performance Liquid Chromatography

As the technology of HPLC has improved over the last decade, it has been more widely applied to the analysis of sterols, with both reversed-phase and normal-phase HPLC having been utilized. Specially synthesized stationary phases with chemically bonded β-cyclodextrin and tomatine have been used in order to attain better separation. The HPLC method has also been applied to the determination of cholesterol in liposome drug products and raw materials.

Since most sterols lack a strong chromophore, UV detection is generally unsatisfactory unless the detector is operated below 250 nm and even as low as 220 nm. Special purpose detectors, such as flame ionization, differential refractometric, and radiochemical have also been employed in order to improve detection.

Okazaki$^{(22)}$ compared the precipitation and direct methods for high-density lipoprotein cholesterol (HDLC) assays with HPLC. The HPLC method, which provided quantitative and qualitative information with high precision, was regarded as being a reliable approach for HDLC assay. The HPLC procedure can be also used to evaluate alternative methods for cholesterol assay.

Rezanka$^{(23)}$ reported the analysis of sterol esters using tandem high-performance liquid chromatography (HPLC/HPLC) and capillary gas chromatography/mass spectrometry (CGC/MS) with CI. Non-polar lipids were
separated by normal-phase HPLC into individual classes and the sterol esters were subsequently separated by RPHPLC. Further separation and identification of the fractions after HPLC were effected by CGC/MS with positive and/or negative CI.

6 ESTROGENS

6.1 Identification Tests for Estrogens

As specified by the USP 23, IR and UV at 200–400 nm are the identification tests prescribed for pharmaceutically important estrogens. The TLC method is used as the identification test for sterile E1 suspension and E2 tablets. For sterile E1 suspension, a 0.25-mm layer of chromatographic silica gel is used and the solvent system consists of a mixture of benzene and acetone (4:1). After developing, the plate is sprayed with dehydrated alcohol and sulfuric acid (3:1), and is then heated at 105 °C for ten minutes.

Their aromatic ring A and the phenolic group at position 3 can characterize estrogens. They show characteristically complicated absorption, with principal maxima at 280 and 342 nm, as well as very strong end absorption down to 200 nm. The pH of the solution is important in determining these phenolic substances. The spectrum of an estrogen with a free phenolic hydroxyl group has an absorption band of medium intensity at around 278 nm. However, at a pH above 9–10, the band shifts about 20 nm higher and the intensity increases owing to the ionization of the phenolic group.

In the IR technique, the potassium bromide pellet method is used. The characteristic group wavenumbers of estrogens are 1613–1610, 1590–1589, and 1503–1490 cm⁻¹ which are due to the C=C or C≡C stretching. The diagnostic value of the absorptions due to the phenolic ring is not comparable with that of the data obtained by UV spectra.

6.2 Assays of Raw Materials and Medicinal Products

Because of their broad therapeutic spectrum, there are numerous pharmaceutical products containing estrogens. As shown in Table 2, HPLC is the most common method used in the analysis of raw materials and medicinal products of estrogens in the USP 23.

6.3 Analysis of Estrogens in Biological Media

Generally, analysis of estrogens in biological material requires extraction of the analyte from the sample, separation into individual components, and their determination. Sometimes it is possible to extract the estrogens from the sample directly by simple solvent extraction but, more often, it is necessary to hydrolyze conjugates

ODS, octadecyl silane; ACN, acetonitrile.
before the extraction. Several methods are available, including acid hydrolysis and enzymatic hydrolysis using β-glucuronidase and/or sulfatases.

There are a number of reports of the use of gel filtration for extracting conjugates. A review of isolation techniques using gel filtration has been published.\(^\text{(24)}\) Separation of individual estrogen gluconides and sulfates was achieved by using diethylaminoethyl Sephadex.\(^\text{(25)}\) Simple extraction of estrogens from plasma or hydrolyzed urine has been achieved by using G-15 and G-25 Sephadex.\(^\text{(26,27)}\)

A number of methods for the extraction of estrogens are summarized in Table 3. Martinetti\(^\text{(42)}\) described a novel extraction method for the evaluation of plasma levels of E2, E1, and E1-S. The method consisted of solid-phase extraction (SPE) followed by a highly specific RIA. The sensitivity of the assay was 0.6 pg mL\(^{-1}\), 2.0 pg mL\(^{-1}\) and 7.0 pg mL\(^{-1}\) for E2, E1, and E1-S respectively.

Hirako\(^\text{(41)}\) reported the establishment of a reliable extraction method of bovine plasma E1-S followed by RIA. E1-S in bovine plasma was extracted with a small reversed-phase cartridge. The steroid conjugate retained in the cartridge was eluted with 40% (v/v) methanol. E1-S was separately recovered from other steroids by the stepwise increase in methanol concentration in the elution solvent. The recoveries of E1-S eluted with 40% methanol were more than 90%. The concentration measured by RIA with the eluent of 40% methanol was consistent for plasma extraction volumes of 0.5–2.0 mL.

Imunoaffinity extraction has been used for liquid chromatographic determination of estrogens. Ikegawa\(^\text{(43)}\) reported an immunoaffinity extraction for the HPLC determination of equilin and its metabolites in plasma. The antibody raised against an equilin 3-O-carboxymethyl-ether-BSA conjugate was characterized as having a high affinity for equilin and equilenin. The adsorbates were recovered by elution with 90% aqueous (v/v) methanol without any interfering peaks on the chromatogram.

Quantification of the estrogen analytes has been accomplished by a variety of methods including colorimetry, fluorimetry, double-isotope derivatization, immunoassay, GC, GC/MS, and HPLC. The early methods may be outdated, but those with low specificity may be combined with modern separation methods like HPLC to offer useful assays. As an example, the quantitative structure–chromatographic retention relationship of six underivatized equine estrogens has been reported.\(^\text{(44)}\)

The immunoassays in use are of the competitive type. Some efforts have been made towards non-competitive immunoassay of estrogens.\(^\text{(45)}\) A wide variety of labels are used, including \(^{125}\)I, \(^{3}H\), enzymes, or fluorescent compounds. Separation of the free and bound analyte can be done using dextran-coated charcoal (DCC), second antibody precipitation, or solid-phase assay. Some form of manipulation can avoid the separation step, e.g. delayed fluorescence. Alternative end-points have enabled some estrogen assays to be simplified and made more sensitive, such as EIA and fluorescence immunoassay (FIA) methods. The detection limits (DLs) achieved are nanograms per litre by RIA and EIA, and micrograms per litre by FIA.

A novel noncompetitive assay for the measurement of estrone-3-glucuronide (EG) in diluted urine was reported by Barnard.\(^\text{(45)}\) The method is based on the use of two

THF, tetrahydrofuran; E1-S, estrone sulfate.
types of antibodies, the β-type and α-type that recognize different epitopes within the variable region of the primary anti-EG antibody (Ab1). The β-type antibody (Ab1) is analyte sensitive and competes with the analyte for an epitope of the primary antibody. On the other hand, the α-type is analyte insensitive, but does not bind the Ab1 in the presence of the β-type due to epitope proximity.

RIA still is the most widely used competitive immunoassay. Combined with chromatographic methods, especially HPLC, RIA is becoming a very powerful tool in the analysis of estrogens. Meanwhile, EIA and FIA have enabled some estrogen assays to be simplified and made more sensitive and have been used as bases for automated immuno-analyzer systems.

An EIA was used by De Lauzon reported the development of a rapid, convenient RIA of E1-S. The assay had a dynamic range of 0.05–90 µg L⁻¹ with a DL of 0.009 µg L⁻¹. Cross-reactivities with structurally related estrogens were <5%.

Lonning described a sensitive assay for measurement of plasma E1-S in patients on treatment with aromatase inhibitors. E1-S was separated, hydrolyzed, and purified as unconjugated E1. E1 was subsequently reduced to E2, purified, and measured by a highly sensitive RIA using E2-6-(O-carboxymethyl) oximino-(2(₃)²¹²I]) iodohistamine as a ligand. The sensitivity limit of the method was 2.7 pM.

Table 4 lists some typical immunoassay methods for the analysis of estrogenic steroids.

### 6.4 Estrogen Analysis by Gas Chromatography

GC has proven extremely useful for the measurement of estrogens in biological fluids, such as plasma and urine. Before the development of the immunoassays, GC with flame ionization detection or, after suitable derivatization, ECD provided highly sensitive methods for estrogen analysis. However, extensive purification is needed before GC analysis. Owing to the presence of hydroxyl groups in their structure, most estrogens are highly polar and require derivatization prior to analysis for complete separation. Derivatization reagents used included TMS ethers, methyloxime ethers, and ethyloxime ethers.

CGC, using stationary phases more polar than those used for neutral steroids, provides improved resolution. Among the polar phases used are OV-210 (McReynolds number 1520), OV-225 (McReynolds number 1813),

and Silar 10c (McReynolds number 3682). These have been successful in separating both human and equine estrogens. Estrogens are identified by retention time and preferably, in addition, by on-line MS. GC/MS has the potential to provide higher sensitivity for analysis as well as confirmation of structure although it is technically the most challenging method for analysis and is not the method of choice for routine analysis. The limit of detection is at the $\mu$g L$^{-1}$ level, comparable to FIA.

Bagnati$^{(54)}$ reported the analysis of diethylstilbestrol, dienestrol and hexestrol in biological samples by immunoaffinity extraction and GC-negative-ion CI MS. Novak$^{(55)}$ reported pregnenolone and E2 identification in some biological samples by means of GC/MS analysis.

Casademont$^{(56)}$ described simultaneous determination, in calf urine, of twelve anabolic agents (including diethylstilbestrol, hexestrol, dienestrol, 17$\beta$-E2, E1, and 17$\alpha$-ethynylestradiol) as heptafluorobutyrl derivatives by capillary GC/MS. Urine samples were extracted with octadecysilica columns and cleanup was performed in two steps with basic alumina and silica SPE cartridges. The extracts obtained were derivatized with heptafluorobutyric anhydride and analyzed by GC/MS. The coefficient of variation obtained was lower than 13%. The limit of detection was 0.5 ng mL$^{-1}$ for all the compounds studied.

### 6.5 Estrogen Analysis by High-performance Liquid Chromatography

HPLC with a suitable choice of column and solvent system can perform estrogen analysis with high specificity. Preparative HPLC has been used to separate steroids prior to analysis by chemical or immunological methods. Reversed-phase LC has been preferred for the separation of the intact conjugated estrogens and is widely used for quality control. The DLs of HPLC using UV detection ranged from 0.5 to 5 mg L$^{-1}$ and were at $\mu$g L$^{-1}$ levels when using a fluorescent detector.

Combining the separation power of HPLC and the selectivity and sensitivity of biochemical assays leads to powerful tools for the assays of compounds in complex matrices, e.g. HPLC combined with RIA in the analysis of estrogens. A novel approach is the use of biochemical interactions, such as a receptor affinity detection system (RAD), as an on-line detector linked to a LC separation column.$^{(57)}$

$\beta$-Cyclodextrins have been investigated as a mobile phase additive to improve the separation of 17-$\alpha$-and 17-$\beta$-E2 and E1,$^{(58)}$ and equilin and three E1 derivatives.$^{(59)}$ In these studies, evidence is presented for inclusion complexation between the model estrogens and $\beta$-cyclodextrins leading to improved resolution and shorter separation time.

Katayama described a sensitive method for the estimation of seven estrogens in plasma.$^{(60)}$ In that method, estrogens were derivatized to esters and the limit of detection was 1–2 ng L$^{-1}$ of plasma. Similar work by Su$^{(61)}$ reported the HPLC analysis of six conjugated and unconjugated estrogens in serum, in which the mobile phase was optimized with ACN and an ion-pairing agent (tetrabutylammonium hydroxide).

An HPLC method for the direct and simultaneous determination of estriol 3- and 16-glucuronides in pregnancy urine was described by Iwata.$^{(62)}$ The method is based on direct derivatization of the glucuronic acid moiety in estril glucuronides in urine with 6,7-dimethoxy-1-methyl-2 ($^1$H)-quinoxaline-3-propionylcarboxylic acid hydrazide. The resulting fluorescent derivatives were separated by column-switching chromatography using a first column for cleanup of the derivatives and a second column for the complete separation of the derivatives. The derivatives were detected spectrofluorimetrically at 445 nm with excitation at 367 nm. The DLs (signal-to-noise ratio $\approx 3$) for estriol 3- and 16-glucuronides were 150 and 180 fmol in a 5 $\mu$L sample of urine (14 and 17 ng mL$^{-1}$ urine), respectively. The method is highly sensitive and simple without any cleanup such as conventional SPE.

### 6.6 Bioassays Using High-performance Liquid Chromatography

On-line coupling of a RPHPLC with a RAD system based on the human estrogen receptor is described by Oosterkamp.$^{(57)}$ The RAD is performed using a postcolumn reaction detection system with open-tubular reaction coils. Estrogens are detected by using a recombinant steroid binding domain of the human estrogen receptor as affinity protein, and a fluorescent estrogen, coumestrol, as reporter molecule. A DL of 5 nmol L$^{-1}$ was achieved for compounds with high affinity for the estrogen receptor, such as 17-$\beta$-E2 and diethylstilbestrol, and 20 nmol L$^{-1}$ for compounds with low affinity. The system can also be operated without requiring a separation step.

HPLC coupled with RIA has been used in the assessment of serum E2 and E1 levels during hormone replacement therapy.$^{(63)}$ It was also reported as a sensitive method in the determination of intratumor E1 and E2 in primary breast cancer tissues.$^{(64)}$

## 7 ANDROGENS

### 7.1 Identification Tests for Androgens

As specified by the USP, IR and UV at 200–400 nm are the identification tests available and common for pharmaceutically important androgens. TLC also has been used as an identification test for some androgens.
### Table 5 Methods used in the assay of androgen-containing medicinals in USP 23

### 7.2 Assays of Raw Materials and Medicinal Products

As shown in Table 5, various methods are used in the analysis of raw materials and medicinal products containing androgens in the USP.

### 7.3 Analysis of Androgens in Biological Media

Androgens, such as testosterone, occur largely in conjugated form in urine, and require the liberation of the steroids before analysis. The methods used include solvolysis at an acid pH for cleavage of steroid sulfates, as well as enzymatic methods, involving the use of β-glucuronidase and sulfatase for cleavage of glucuronides and sulfates.

Solvents that are partially miscible or immiscible with water, such as ethyl acetate, ether, chloroform, and dichloromethane, have been used to extract “free” (unconjugated) steroids from biological matrices. In addition, ion-exchange resins, such as Amberlite XAD-2, have been utilized extensively for extraction and subsequent separation of steroid hormones, both “free” and conjugated.

Gel filtration has also proven to be extremely valuable. Since 1980, SPE cartridges have been used widely as adsorptive extractants. After application of the urine sample, most of the interfering substances are washed away with water while the analytes remain adsorbed. Elution with a stronger solvent, such as methanol, removes the analytes. As little as 2 mL of methanol is needed to provide some 98% recovery of steroids with SPE cartridges. However, some workers have reported that the eluates from these contain impurities that interfere with subsequent GC/MS quantification of steroids. Some researchers prefer to use HPLC for final purification.

Once the steroids and/or steroid conjugates have been extracted from the biological matrix (whether by liquid or solid extraction), an initial separation into steroid classes (if only unconjugated compounds are to be analyzed) or into “free” steroids, glucuronides, mono- and di-sulfates may be required. HPLC, capillary GC, and TLC have been widely used in the separation and quantification of androgens as described below.

Using high-performance TLC plates, a complete separation of androgens and their metabolites with methylene chloride–cyclohexane–acetone (70:25:5, v/v/v) has been reported. Following derivatization of the steroids while still on the plates by cinnamic aldehyde, 4-dimethylaminobenzaldehyde, and sulfuric acid, quantitative determination was achieved by fluorescence.

Since some steroids are difficult to resolve by TLC, special modifications, such as multiple running (using the same system twice or different systems) or two-dimensional TLC, were tried in order to improve separations. Appreciable increases in resolution were achieved, but at the sacrifice of speed.

In GC, the use of capillary columns has resulted in improved resolving power over packed columns and has proved invaluable in analyses of extracts of various biological fluids.
In order to increase volatility and improve heat stability in GC, many substances have been used as derivatizing agents. Among these have been the O-methyl oximes for derivatization of ketonic functions and the TMS ethers for hydroxyl functions.[76,77] Others have used the oxime instead of the O-methyl oxime, coupled with TMS ethers.[78] For hydroxyl group derivatization, alternatives to TMS ethers are the t-butyldimethylsilyl (TBDSMS) ethers.[69] Other derivatives available for steroid hydroxyl groups are acetates[79] or trifluoroacetates.[80]

### 7.4 High-performance Liquid Chromatography

The most important uses of HPLC have generally been the separation and measurement of steroids in tissue preparations and perfusates, or synthesized in chemical reactions, and also for analysis of extracts of steroids endogenous to tissues such as the adrenals and testes. Moreover, HPLC has been valuable in the purification of steroid-containing extracts prior to immunoassay, being particularly useful in situations where high-specificity antisera are not available.

Makin and Heftmann[81] have reported on the application of HPLC to the analysis of C21, C19, and C18 steroids. The technique has not been used extensively for the quantification of C19 steroids in human body fluids, because the majority of detectors normally used with HPLC cannot measure the low concentrations often present. To overcome the problem of the relative insensitivity of UV detection at 240 nm, Payne[82] used specific bacterial hydroxysteroid dehydrogenases for detection and quantification after HPLC separation of serum steroids.

In attempting to improve resolution of steroids or to reduce the overall elution time for a chromatographic run, while still retaining acceptable resolving power, reports of various modifications to HPLC technology, such as using multistep gradient elution and using microbore columns, have been published.[83,84]

### 7.5 Mass Spectrometry

Coupled with capillary GC or HPLC, MS has been extensively employed in androgen analysis. The techniques used included MS with selected ion monitoring (SIM), metastable peak monitoring, and MS/MS. Fast atom bombardment/mass spectrometry (FAB/MS), after separation by HPLC, has been used in the quantification of intact conjugates without the need for prior hydrolysis.[85]

GC/MS has been useful in studies of metabolism and biosynthesis of androgens.[86,87] Moreover, GC/MS is proven to be a simple analytical screening procedure for the estimation of total androgen conjugates in post-competition urine inspection.[88–89] Hartmann[90] reported that DLs of 0.02–0.1 g kg⁻¹ were reached by GC/MS (EI) in the SIM mode. Cairns[91] described the analysis of testosterone esters by MS/MS.

### 7.6 Immunoassay of Androgens

In addition to its utility for routine analysis of androgens in clinical laboratories, RIA has also been used in analytical and biosynthetic studies in vitro or in vivo.

Separation of the various forms of testosterone has been accomplished by various methods. Older procedures such as equilibrium dialysis (EOD),[92] centrifugal ultrafiltration,[93] and ammonium sulfate precipitation have been modified to increase reproducibility and permit analysis of large numbers of samples.[94]

Since RIA is by nature a heterogeneous technique, the separation of bound and free analyte is necessary for accurate counting. In addition to protein precipitation, DCC has been used extensively, as well as hydroxylapatite.[95] However, these methods prolong the assays and reduce the possibility of automation. Fiet[96] described a technique called scintillation proximity assay (SPA), which eliminates the separation of bound and free steroid in RIA.

Improvements in EIAs, such as enzyme-linked immunosorbent assay (ELISA), for testosterone and other C19 steroids, which give greater sensitivity, improved validation, and reduction of non-specific binding, have been published. These improvements have been achieved by the use of various reporter enzymes, such as alkaline phosphatase, HRP,[98] β-galactosidase, and penicillilnase.[99]

For FIAs, the most common labels are coumarin derivatives and fluorescein. The disadvantage of these and many other fluorescent compounds is that they give high background signals. In order to resolve this difficulty, time-resolved fluorometry, using the chelates of the lanthanides europium, samarium, and terbium has been developed.[100,101] This method is capable of providing FIAs with sensitivities of 10⁻¹⁵–10⁻¹⁶ mol L⁻¹.

### 8 PROGESTINS

The main clinical use of assays for progestins is determining whether a woman has probably ovulated in a given cycle and if the luteal phase is adequate for pregnancy to be possible. The determination of synthetic progesterones has become important owing to their increasing uses as contraceptive agents. The quantification of neurosteroids (steroids in brain), of which pregnenolone is one of the most important, has evoked intense interest and has been done by RIA, GC/MS, and HPLC.[102,103]
8.1 Identification Tests for Progestins

For pharmaceutically important progestins, IR and UV at 200–400 nm are the most frequently used identification tests specified by the USP 23. In the IR techniques, the potassium bromide pellet method is used.

In the UV technique, the Δ^4-3-keto group is the characteristic chromophoric group in progestins. The conjugation band is fairly intense (λ_{max} 240 nm, ε ~ 1.7 x 10^4 L mol^{-1} cm^{-1}). The effect of the second double bond at the Δ^5 position is significant, causing about a 40 nm bathochromic and a considerable hyperchromic shift, e.g. megestrol acetate.

In IR spectra, progestins show bands of medium intensity (1635–1605 cm^{-1}) due to unsaturation as α,β-unsaturated ketones. Together with the carbonyl absorption (1680 cm^{-1}), this is one of the best ways to identify progestins. More detailed correlations of progestin IR bands are available in the literature.(1)

8.2 Assays of Raw Materials and Medicinal Products

Assays of progestins as raw materials and in medicinal products are summarized in Table 6. UV is not only an important detection mode in HPLC, but also is a useful analytical method for identification purposes although it may require suitable derivatization of the analyte.

8.3 Analysis of Progestins in Biological Media

Generally, analysis of progestins in biological material requires extraction of the analyte from the sample, separation into individual components, and their subsequent determination. Although extraction is time-consuming and expensive, it is often necessary because it can increase the specificity and sensitivity of the final assay system by reducing the matrix effect. In some cases, good correlation and agreement between direct and extraction methods have been demonstrated.(104)

The extraction of the progestins from the biological material is dependent on the matrix involved. In some cases, it is necessary to hydrolyze conjugates, e.g. glucuronides and sulfates, with enzymes before extraction. There is usually a compromise on the polarity of the extraction solvent; the less polar extraction reagents will give the lower extraction efficiencies for progesterone but will also reduce interferences from unwanted polar cross-reactants.

Meng(105) reported a method for combined analysis of conjugated progesterone metabolites and bile acids in serum and urine of pregnant women, which put emphasis on extraction and separation. Total neutral steroids were extracted with ODS-bonded silica. Groups of conjugates were separated on the lipophilic ion-exchange triethylaminoxypropyl Sephadex LH-20 (TEAP-LH-20). Sequences of hydrolysis/solvolyis and separations on TEAP-LH-20 permitted separate analyses of steroids, glucuronides, monosulfates, and disulfates. Extraction and solvolysis of steroid conjugates were monitored by FAB/MS.

Clouet(106) described the identification of endogenous 19-nortestosterone in pregnant ewes by GC/MS. SPE and liquid–liquid extraction were used in that method. In addition, G60 purification and HPLC purification were used to increase the sensitivity of the final assay.

The quantitative determination of pregnanolone in rat brain was achieved by RPHPLC with fluorescence

detection using 1-anthroyl cyanide as the derivatization reagent and the internal standard method. The desired fraction was obtained from a rat brain with the combined use of a Bond Elut C8 cartridge for the SPE and lipophilic gel (piperidino-hydroxypropyl Sephadex LH-20) for the ion-exchange chromatography. The achieved DL was 0.2 ppb (initial volume: 20 mL).

These and other common methods for the extraction of progestins are summarized in Table 7.

8.4 Measurement of Progestins

Presently, determination of progestins is mainly performed by immunoassays and less frequently by other methods such as HPLC, GC, and GC/MS. Competitive immunoassays are the principal methods for progestin measurement. A wide variety of labels are used, including $^{125}$I, $^3$H, enzymes, or fluorescent compounds. Separation of the free and bound analyte use methods based on affinity and methods based on coupling of the antibody to some form of solid phase, such as DCC absorption, as well as ammonium sulfate precipitation, and second antibody precipitation.

Use of nonisotope labels has enabled some progestin assays, such as EIA and FIA, to be simplified and made more sensitive. Currently available automated procedures for plasma progesterones utilize a similar principle with a progesterone-peroxidase conjugate. Table 8 shows some examples of immunoassays reported for the analysis of progestins.

8.5 Progestin Analysis by Gas Chromatography

GC was established as the most sensitive method for the measurement of progestin in the 1960s. At that time, the maximum sensitivity was 0.1–0.2 ng mL$^{-1}$, although specificity was dependent on the efficient separation. Improvements were subsequently made by

TME, tyrosine methyl ester.
employing more sensitive detection systems, including argon ionization (130) flame ionization (131) and electron capture, (132) which used various derivatization reagents including chloroacetate, chlorodifluoroacetate, and hepta-fluorobutyrate in order to increase the sensitivity of electron capture. Lucis (133) has reviewed several GC procedures for the determination of urinary pregnanediol. The methods involved enzymatic hydrolysis, column chromatography on alumina, and separation and quantitation by GC as free steroids or by formation of derivatives.

Pommier developed an analytical method for the determination of NETA in human plasma by capillary GC/MS with testosterone acetate as the internal standard. (109) The compounds were converted into their pentafluoropropionyl derivatives before determination. The GC/MS used a mass selective detector at m/z 486 for NETA. The detection range was 0.10–10 ng mL⁻¹.

Mathur (102) described a GC/MS method for identification and quantification of brain steroids and their conjugates, which includes pregnenolone, 3β-hydroxy-5α-pregnan-20-one, and 3α-hydroxy-5α-pregnan-20-one. The steroids exist as unconjugated compounds and as sulfates, lipoidal esters, and sulfolipids.

Simultaneous determination of NET and six metabolites in human plasma was achieved by capillary GC/MS. (110) The compounds are determined after enzymatic hydrolysis and conversion to bistrimethylsilyl derivatives. The reproducibility and accuracy of the method were found suitable, over the range 0.5–8 ng mL⁻¹ for NET and five of the metabolites.

Table 9 summarizes the progress made in the analysis of progestins by GC.

8.6 Progestin Analysis by High-performance Liquid Chromatography

HPLC is an excellent analytical method, but derivatization may be necessary to increase the response of progestins because they are not very responsive to the commonly used detectors. Compounds with poor detector response can be determined using indirect UV or fluorescence detection. In this technique, a UV- or fluorescence-absorbing species is added to the mobile phase and the detection results from the reduction in response of the probe on elution of the sample. RPHPLC is the main mode used in the indirect detection of both charged and uncharged species. In HPLC, β-cyclodextrins have been used either chemically bonded as a stationary phase or added to the mobile phase. It has been postulated that inclusion complexation between the progestin and β-cyclodextrin leads to improved resolution and shorter separation time. Lamparczyk (58) investigated the influence of mobile-phase composition, concentration of β-cyclodextrin, and temperature in the HPLC separation of norgestrel. Enantiomers were detected by using UV detection at 240 nm. The results showed that chiral recognition is maintained at 20°C, baseline separation is observed at 0°C, and the best chiral separation was achieved in the range from −5°C to 0°C.

The quantitative determination of pregnenolone in rat brain was achieved by RPHPLC with fluorescence detection using 1-anthroyl cyanide as the derivatization reagent and the internal standard method. (103)

Agnus (136) reported the indirect photodetection of pregnenolone by HPLC on a Cyclobond column using UV detection at 280 nm and testosterone as the internal standard. A UV-absorbing species (testosterone) was added to the mobile phase and detection resulted from the perturbation of the distribution equilibrium of the probe on injection of the sample. This method can be used as an alternative for the detection of poorly UV-absorbing species, but both the sample and the marker must interact with β-cyclodextrin.

Gorog (137) described the role of HPLC/diode-array UV spectroscopy in the identification of minor components

(impurities, degradation products, metabolites) in various matrices of progestin drug products. Hydroxylated impurities (degradation products) of norgestrel (6α and β, 10β-hydroxyl derivatives) were identified on the basis of their UV spectra and retention time matching with synthesized impurities.

Table 10 summarizes some representative HPLC methods.

9 CONTRACEPTIVES

Since contraceptives contain only estrogens and progestins, the methods for the combinations are similar to those described under previous topics.

Dorantes(138) reported a modification of the USP dissolution method for the analysis of norethindrone and ethinyl E2 tablets. Jiang(139) reported the HPLC analysis of injectable contraceptive preparations containing NET enanthate and E2 valerate.

The separation of seven ethynyl steroids registered as oral contraceptives by micellar electrokinetic chromatography (MEKC) has been described by Poole.(140)

10 CORTICOSTEROIDS

Because of the serious side effects associated with the medicinal use of corticosteroids as anti-inflammatories, many analogs are available and are official in the USP 23. Assays of corticoid raw materials specified in USP are shown in Table 11.

In the search for corticosteroids with improved therapeutic profiles, a great many compounds have been developed that are closely related structurally and have very similar physical properties. These similarities give rise to unique difficulties in accurately analyzing for the corticosteroids in their medicinal products and, more importantly, in biological matrices where their levels are diagnostic for many pathological processes. For these reasons, corticosteroid assays require effective separation techniques, as well as specific and selective detection methods. Since the concentrations in biological matrices are small, sensitivity is also an important requirement in order to lessen estimation error.

Acceptable separation efficiency can be achieved in many cases by simple extraction or back-extraction with suitable solvents. If this is not sufficient, a chromatographic step may be necessary using TLC, paper chromatography, column chromatography, or HPLC. CE has also proven to be a valuable separation modality.(6,141) The last two methods show the most promise for clinical analyses where speed and the potential for automation are important.

Since most of these steroids have acceptable absorptivities, detection can be done efficiently by UV spectroscopy. In more difficult situations, immunoassays, such as RIA, can improve sensitivity. The use of a mass spectral detector after separation by GC or HPLC yields not only sensitivity but also specificity through the use of SIM.

10.1 High-performance Liquid Chromatography

Normal- and reversed-phase HPLC operating in a wide polarity range have been developed for the rapid screening of natural and synthetic corticosteroids. The developments in HPLC analysis of corticosteroids for the determination of clinically important steroids in biological specimens have been reviewed.(142,143) Various sample preparation techniques were also described.

Takeda has developed a chemiluminescence high-performance liquid chromatographic method for the determination of corticosteroids and tetrahydrocortico-steroids.(144) Garg(145) described the simultaneous analysis of prednisone, prednisolone, and their major hydroxylated metabolites in urine by HPLC. A rapid HPLC analysis and stability study of hydrocortisone 17-butyrate in cream preparations is described by Wanwimolruk.(146) Chen(147) reported the stereochemical analysis of betamethasone and dexamethasone by derivatization and HPLC.

10.2 High-performance Liquid Chromatography/Mass Spectrometry

Render(148) reported the electrospray mass spectroscopic characterization of a nonpolar 18-hydroxy-11-deoxy corticosterone dimer. The dimer was purified by HPLC and further analyzed by electrospray MS.

Fiori(149) reported the identification of corticosteroids as illegal feed additives in milk replacers by LC/MS using CI. SPE (C₁₈), C₈ column separation, and data acquisition (positive ions) in the scan range m/z 200–550 were used to differentiate and identify compounds at levels in the range of 20–100 ppb.

10.3 Gas Chromatography/Mass Spectrometry

GC/MS provides excellent sensitivity as well as improved specificity and a number of reports of its use have been published. Several techniques have been developed for cortisol using both radiolabeled and stable-isotope dilution methods.(150,151) The technique can also be used for the determination of cortisone in human plasma.(152,153)

10.4 Immunoassay Combined with High-performance Liquid Chromatography and/or Gas Chromatography

Delahau(154) reported the quantitative determination of several synthetic corticosteroids by GC/MS after purification by immunoaffinity chromatography. Primary extracts from different matrices (liver, milk, urine, and feces) were first purified on C₁₈ cartridges. The CI negative ionization mode was used. The estimated detection and quantification limits were, respectively, 0.25 and 0.5 ppb or lower.
In order to increase selectivity of the assay of corticosteroids and simplify the sample pretreatment procedure, Lovgren\(^{155}\) evaluated MLC using Tween 20 as surfactant preceding immunoassay. It was shown that the separation was dependent on several parameters, such as temperature, the concentration of Tween 20, pH and ionic strength of the mobile phase, and nature of the stationary phase.

10.5 Micellar Electrokinetic Capillary Chromatography

Wiedmer\(^{156}\) has discussed the successful combination of MEKC with electrospray ionization mass spectrometry (ESIMS) for the analysis of some corticosteroids. Optimization of the surfactant concentration and the length of the injected micellar plug were necessary for efficient analysis.

Bumgarner\(^{157}\) enhanced separation of corticosteroids by using mixed micelles of short-chain alkyl surfactants and bile salts in electrokinetic chromatography. It was found that separation patterns are mostly influenced by the number of hydroxyl functional groups on the steroidal backbone of the bile salts, while the type of ionic head group has little effect on the steroid separation. And the addition of the short-chain alkylsulfonate sodium butanesulfonate to the mixture of taurocholate and glycodeoxycholate greatly improved the separation of the 17 corticosteroids and provided a baseline separation of all solutes.

Nishi\(^{141}\) achieved the separation and determination of lipophilic corticosteroids and benzothiazepin analogs by MEKC using bile salts.

11 CARDIAC STEROIDS

Since the medicinal properties of the Digitalis species have been known for centuries, there has always been considerable interest in analytical methods. Formerly, the assays in plants and pharmaceutical preparations utilized colorimetric and fluorometric assays. More modern methods are used for the medicinal agents containing the major alkaloids of the Digitalis species, digoxin and digitoxin, which are official in the USP. Analyses of these products are all done in a similar manner, by RPHPLC using ODS columns with 3–5 µm packing and UV detection at 218 nm.

Since there is a small margin between therapeutic and toxic concentrations in body fluids, more sensitive methods such as RIA, which was originally developed for digoxin analysis, and fluorescence polarization assay were required. However, HPLC is superior for the separation of digitalis metabolites, which often cannot be differentiated by immunological methods because of considerable cross-reactivity with the antibody. In order to improve sensitivity, the HPLC method is often combined with RIA and fluorescence polarization immunoassay (FPIA) detection. Embree\(^{158}\) compared digoxin analyses by HPLC/postcolumn derivatization and FPIA.

11.1 Separation and Purification

Ikeda\(^{159}\) developed an analytical method for the determination of cardiac glycosides in Digitalis lanata leaves by RPTLC. The procedure consisted of extraction of dry leaf powder with 50% methanol and cleanup by Sep-Pak cartridges prior to RPTLC analysis on an octadeceylsilyl bonded silica gel plate, using a developing solvent of ACN–methanol–0.5 M NaCl (1 : 1 : 1). They also reported a quantitative HPLC method for analysis of cardiac glycosides in Digitalis purpurea leaves.\(^{160}\)

11.2 Immunoassays

Miles\(^{161}\) described the determination of salivary digoxin with a dry strip immunoassay. Analysis of salivary digoxin using a rapid dry chemistry, enzyme-labeled immunometric assay (ELIA) was compared with FPIA. There were no significant differences found between ELIA and FPIA determinations of salivary digoxin, serum digoxin, or salivary/serum concentration ratios.

Lovgren\(^{162}\) described the application of new non-competitive flow injection EIAs for determination of digoxigenin. Antibody fragments reacting with digoxigenin and labeled with alkaline phosphatase, were used to convert 4-methyl umbelliferyl phosphate to a fluorescent product measured downstream.

Oosterkamp\(^{11}\) reported analysis of digoxin and its metabolites by using FIA as an on-line postcolumn detector coupled to HPLC. In a later study, he further discussed different strategies for using this technique.\(^{19}\)

11.3 High-performance Liquid Chromatography

Belsner\(^{163}\) developed a postcolumn derivatization method for the fluorescence detection of cardenolides in RPHPLC by fluorescence derivatization of cardiac glycosides with concentrated acids. The column effluent is blended with concentrated acids in a knitted tube reactor, accelerated by Cu(II) acetate or Co(II) nitrate in H₂SO₄. Cardiac glycoside levels of less than 100 pg glycoside in 1 mL of plasma are detectable.

Wolffender\(^{164}\) studied cardenolide glycosides in crude plant extracts by LC combined with thermospray and continuous-flow FAB/MS.
Steroid Analysis

11.4 Thin-layer Chromatography

Ponder(165) developed a method for the determination of digoxin and related compounds in digoxin drug substance and tablets by using HPTLC. Separation of the three compounds was accomplished on a C18 reversed-phase plate using water–methanol–ethyl acetate (50:48:2) as the mobile phase. The analytes were determined by densitometry using absorbance for digoxin and fluorescence for the related compounds.

11.5 Micellar Electrokinetic Chromatography

Debusschere(166) describes the influence of some parameters, such as, concentration of surfactant, pH, and addition of organic modifiers and urea on the resolution of four cardiac glycosides by MEKC. Efficiency was improved with a shorter analysis time.

12 VITAMIN D

Vitamin D exists in two forms, vitamin D2 (ergocalciferol), which is found in yeast and formed from ergosterol by irradiation, and vitamin D3 (cholecalciferol), which is found in fish oils and is also formed in animal tissue by irradiation of 7-dehydrocholesterol. These compounds are very similar structurally, each exhibiting an open B ring due to scission of the bond between the 9 and 10 carbons. They have minimal biological activity and are metabolized to 25-hydroxyvitamin D (25-OHD3), which is more active, and 1,25-dihydroxyvitamin D (1,25-(OH)2D3), which is still more active. The concentrations of 25-OHD3 and 1,25-(OH)2D3 reflect the nutritional state of the individual and, therefore, their quantification becomes important in the diagnosis of patients with calcium and phosphate deficiency.

12.1 United States Pharmacopeia Analysis

The USP 23 contains two alternative assays for the vitamins D, one chemical and one chromatographic (HPLC). Because of the complicated formulations of most vitamin preparations and the instability of vitamins D to air and light, both require extensive cleanup and separation procedures. In the chemical method, the sample is first saponified in alkaline solution, extracted with ether, and passed successively through two glass chromatographic columns, one containing siliceous earth, and the other Fuller’s Earth. A color is developed in the purified extract using antimony trichloride–acetyl chloride reagent. Absorbance is measured at 500 and 550 nm.

In the HPLC method, the sample is saponified and extracted, then passed at high pressure first through a reversed-phase cleanup column containing an octyl stationary phase. Then the fraction containing vitamin D is passed through a normal-phase column containing porous silica microparticles. Detection is by UV absorption at 254 nm.

12.2 Gas Chromatography

GC has been used successfully to analyze for vitamins D2 and D3. However, the procedure is not without problems. The first of these concerns the formation of the pyro and isopyro forms in which the B ring is closed between the 9 and 10 positions as a result of the high temperature environment in the chromatograph. The isomers can be separated using packed columns of medium polarity. The second problem concerns the polarity of the compounds and their metabolites, which are increasingly hydroxylated and usually require derivatization in order to assure separation and detectability. Silylation of hydroxyl groups and oximation of keto functions are the common methods. Use of GC/MS with these derivatives for the measurement of plasma concentrations has been described for all the major vitamin D metabolites.(167)

12.3 High-performance Liquid Chromatography

HPLC separations are usually monitored by the use of UV detectors, since all vitamin D metabolites have an absorption maximum of 264 nm with molar absorbivities on the order of 18 000. In order to enhance the sensitivity of detection of peaks emerging from an HPLC column, other forms of detection have been investigated and one, using fluorescence detection, provides significant improvement in sensitivity. Vitamin D and its metabolites are not themselves fluorescent and in order to utilize this methodology some precolumn derivatization is required. A number of methods for 25-OHD3 using the formation of fluorescent triazoline adducts have been described.(168,169) The use of substituted 1,2,4-triazoline-3,5-dione (TAD) as a reagent for the protection of the vitamin D cis-triene structure during chemical synthesis or modification has been known for many years.(170)

Masuda(171) reported a highly sensitive HPLC assay method using an electrochemical detector for assays of vitamin D metabolites. The assay involves extracting lipids from plasma with methylene chloride and methanol, purification on Zorbax SIL column with 5.5% (v/v) isopropanol in hexane, and quantification by HPLC coupled to ECD. A coulometric system, composed of the dual electrode analytical cell and a guard cell, was used for electrochemical detection of the eluting compounds. The DL was approximately 50 pg mL−1 for 25(OH)D3 and 24,25(OH)2D3 in plasma.
13.4 Protein Binding Analysis

The majority of binding assays for vitamin D and its metabolites rely on some form of saturation analysis using plasma binding proteins, intracellular receptor proteins, or antibodies as the binding proteins. Two sensitive RIAs have been described. A comprehensive list of these methods is given in a number of reviews.

13.5 Mass Spectrometry

HPLC can be directly linked to a mass spectrometer (HPLC/MS), and there have been descriptions of the use of thermospray LC with MS for vitamin D metabolites. A method for investigating the conjugates of vitamin D₃ using FAB/MS has been described. Litwiller used FAB/MS to prove the existence of a monoglucuronide of 1,25-(OH)₂D₃.

13. BILE ACIDS

Bile acids, e.g. cholic acid, are formed in the liver from cholesterol and, therefore, have structural similarities, although they are more highly hydroxylated. They are conjugated in the liver with nitrogenous bases, e.g. glycine and taurine, to yield the bile salts glycocholate and taurocholate. These may also be sulfated and/or glucuronidated. They are excreted into the intestine to emulsify fats for digestion and then reabsorbed and returned to the liver. This process is called enterohepatic recirculation and occurs ten to twelve times a day. Since these processes are so intimately associated with liver and intestinal function, the clinical analysis of bile acids is important in the diagnosis of certain liver or intestinal disorders. Also their assays have been used for probing the complex pathways of cholesterol metabolism.

13.1 Analysis of Bile Acids in Biological Media

Because any biological sample contains a complicated mixture of acids, salts, and conjugated metabolites, efficient extraction from the sample matrix is essential. Since all forms are ionic, the use of an ion-exchange resin such as XAD-2 has been reported to be suitable. SPE cartridges containing octadeclsilil silica have been used.

Once extracted from their biological matrix, bile acid mixtures may be fractionated into unconjugated, conjugated, sulfated, and glucuronidated moieties. Alme described a method using gel chromatography with Sephadex LH-20, but Setchell found it was first necessary to subject the extract to a cation exchanger to improve separation. Further separation may be achieved using GC or HPLC. Chaplin reported that bile acids and their conjugated forms also may be separated by anion-exchange chromatography in alkaline media (0.9 M sodium acetate, 0.1 M sodium hydroxide, and 15% v/v ACN) on a CarboPac PA-100 column.

13.2 General Methods

The most important techniques currently used to measure bile-acid concentrations include enzymatic, GC, GC/MS, HPLC, HPLC/MS, and capillary zone electrophoresis (CZE). Scalia has reviewed the major chromatographic techniques and combined detection systems for the determination of bile acids.

13.3 Enzymatic Analysis

An enzymatic TLC method used the enzyme 3α-hydroxysteroid dehydrogenase to determine total bile acids with a free 3α-hydroxy group. Since the enzyme does not work with bile acids which are sulfated, glucuronidated, or esterified at the C-3 position, it may be necessary to include a preliminary hydrolysis procedure. It is also a convenient way to distinguish between free and conjugated analytes. Further work indicated that, in order to enhance resolution in the analysis of human bile, it was essential to extract with an anion-exchange resin prior to HPLC. In a similar manner, Kato described an enzymatic determination of serum 3α-sulfated bile acids concentration with bile acid 3α-sulfate sulfohydrolase.

13.4 Gas Chromatography

Even since the development of efficient HPLC procedures for bile acids, CGC has provided an excellent method for bile acid analysis, especially when combined with MS. However, since bile acids found in biological matrices are hydroxylated and conjugated, preliminary treatment is necessary to hydrolyze them and increase their volatility. Hydrolysis can be accomplished in acid solution or by using sulfatase or glucuronidase enzymes. Derivatization involves silylation, methylation, or reduction with LiAlH₄ for hydroxyl groups and oximation for keto groups. Street has reported on capillary column GC methods for the determination of major bile acids at very low concentrations in human serum and urine. However, since urinary bile acids are conjugated to a greater extent than serum bile acids, preliminary treatment of the urine is necessary to hydrolyze and derivatize them to increase their volatility. Owing to its ability to achieve greater specificity, GC/MS is a superior method for urinary bile acids.

13.5 High-performance Liquid Chromatography

Despite the excellent resolving power of HPLC, bile acids have been difficult to separate because of their structural
similarity and extensive hydroxylation. In addition, bile acids do not have strong UV chromophores detectable at wavelengths higher than 220 nm and they also do not have strong fluorophores. In order to increase resolution and sensitivity, pre- and postcolumn derivatization methods have been developed. Precolumn derivatization procedures included the use of 4-bromoethyl-7-methoxy coumarin,\(^ {189}\) 1-bromoaethylpyrene,\(^ {190}\) 1-anthroyl nitrite,\(^ {191}\) and dansylhydrazones.\(^ {192}\) Cav-rini\(^ {193}\) used 2-bromoacetyl-6-methoxynaphthalene as a prechromatographic fluorescent-labeling reagent for the HPLC analysis of bile acids. Gulutuna\(^ {194}\) accomplished a sensitive and precise separation and measurement of commonly occurring free and conjugated bile acids in serum, liver biopsies, bile, gastric juice, and feces using HPLC with fluorescence labeling. Sakakura\(^ {195}\) developed a method for the simultaneous determination of bile acids in rat bile and serum by RPHPLC with post-column enzymatic reaction and fluorescence detection. Without prior fractionation and alkaline hydrolysis, 26 unconjugated or conjugated bile acids were determined. The limits of detection were 1–5 pmol.

Kurosawa\(^ {196}\) reported an analysis of stereoisomeric C\(_{27}\)-bile acids by HPLC with fluorescence detection. The method involved the derivatization of the C\(_{27}\)-bile acids into fluorescent esters with 3-(4-bromomethylphenyl)-7-diethylaminocoumarin. The separation of the 16 kinds of bile acids containing stereoisomers was carried out using a reversed-phase Inertsil C\(_{8}\)-column by gradient elution. The DLs were about 15 fmol.

Bile salts are all surface-active agents and, as such, their ability to solubilize fats in the intestine depends on their hydrophilic–hydrophobic balance, more commonly called hydrophilic–lipophilic balance (HLB). Scholmerich\(^ {197}\) attempted to correlate HLB with the octanol–water partition coefficient. This can be done either by direct octanol–water partition experiments or by RPHPLC using an octyl (C\(_{8}\)) column. Partition coefficients appear to be influenced strongly by the number of hydroxyl groups present on the sterol nucleus and only weakly by the orientation of the groups. In contrast, capacity factors are very sensitive to differences in orientation of ring hydroxyls.\(^ {198}\)

13.6 Mass Spectrometry

Fast atom bombardment spectrometry has been coupled with collision-induced fragmentation for the analysis of taurine-coupled bile acids.\(^ {199}\) Unconjugated, glycine-conjugated, sulfated, and glucuronidated bile acids are first coupled with taurine by using a carbodiimide reagent. The taurine-conjugated bile acids give more intense spectra than the original parent compounds. MS coupled to HPLC for the analysis of bile acids in biological fluids also has been reported.\(^ {200}\) Warrack\(^ {201}\) described ion spray liquid chromatographic/mass spectrometric characterization of bile acids.

13.7 Capillary Zone Electrophoresis

Yarabe\(^ {202}\) demonstrated that CZE with indirect photometric detection is a viable approach to the separation and identification of free bile acids along with their taurine and glycine derivatives. Various parameters such as pH, organic solvent concentrations, column temperature, and type of chromophore electrolyte were investigated to optimize the electrophoretic separation and to maximize the peak capacity. The quality of separation of bile acids can be dramatically improved by incorporating \(\gamma\)-cyclodextrin (\(\gamma\)-CD) in the running electrolyte. As a result, a CZE separation of all 15 bile acids was possible in approximately 30 min using 5 mM-adenosine 5-monophosphate, 7 mM \(\gamma\)-CD in 75% (v/v) methanol at pH 7.0 (apparent).

1 INTRODUCTION

The many variations and permutations of infrared (IR) and Raman spectroscopies are collectively known as “vibrational spectroscopy”. The unifying feature underlying all of the vibrational spectroscopies is that the effects being measured are related to molecular motion (i.e. stretching or bending of atoms in a molecule, lattice vibrations, etc.). Vibrational spectroscopy, in one form or another, has been exploited to provide both quantitative and qualitative information about pharmaceutically important samples for decades, despite the sometimes complex nature of the spectral data obtained. The purpose of this chapter is to provide the interested reader with a broad overview of the subject area, the background necessary to understand the application of vibrational spectroscopy to samples of pharmaceutical importance, to review representative recent applications and provide a broad array of corresponding references to facilitate more in-depth inquiry.

The first experience which most students in one of the chemically related sciences have with vibrational spectroscopy occurs in an introductory organic chemistry laboratory. The student’s first IR spectrum is generally acquired for a solid or liquid sample either synthesized in the laboratory or provided as an “unknown” by the instructor. The amount of light absorbed (or transmitted) by the sample in the MIR region of the spectrum is recorded using a suitable instrument after generally limited sample preparation. The student’s knowledge of IR spectroscopy is often limited to having learned in class that the wavelengths at which the compound absorbs IR radiation are indicative of the chemical functionalities in the sample. Once a spectrum is acquired the student is directed to one of the many IR wavelength versus functionality correlation charts found in textbooks. Depending on the number and type of functionalities in the sample, the complex spectral pattern obtained can prove to be overwhelming to the student. Using both positive information (the sample absorbs light in a region indicative of a given functionality) and negative information (the sample does not absorb in the region indicative of another functionality), the student completes his/her first experience in vibrational spectroscopy by listing those functionalities which are probably present in the sample and those functionalities which are probably absent. Another common approach taken by students to determine the likely identity of the sample, or at least to narrow down the possibilities, is to manually compare the spectral data obtained with the spectra contained in a collection of spectra, either on paper or computer readable format. Thus, the concepts of spectral interpretation and spectral matching are also
usually part of the student’s introduction to vibrational spectroscopy. The training for most nonchemistry and many chemistry students at both the undergraduate and graduate levels will not include in-depth discussions of other types of vibrational spectroscopy (i.e. NIR, Raman), more complex sample and data-handling techniques or general discussions of other than routine applications of vibrational spectroscopy to structure identification.

The unifying characteristic of all of the types of spectroscopy that come under the general heading of vibrational spectroscopy is that they measure the effect that electromagnetic radiation has on the molecular vibrations of the sample. The reader is cautioned, however, that one of the confusing aspects of vibrational spectroscopy is that different units, i.e. either wavenumbers (cm$^{-1}$) or wavelength (µm, nm), are used by practitioners of the various methods. The most common units in current use are presented here for comparison.

The energies required to induce transitions between vibrational levels range from the low-energy photons of the far infrared (FIR) (10–200 cm$^{-1}$ or 1000–50 µm), to the moderate-energy photons of the MIR region (200–4000 cm$^{-1}$ or 50–2.5 µm), to the higher-energy photons of the NIR region (14 300–4000 cm$^{-1}$ or 0.7–2.5 µm or 700–2500 nm). It is worth noting at this point that most MIR instruments have an upper limit which extends beyond 4000 cm$^{-1}$ but have a lower limit of 400 cm$^{-1}$. Low-energy FIR photons are used to probe the low-energy transitions of the sample, for example the lattice vibrations of a polymer. MIR photons are sufficiently energetic to promote changes from the ground vibrational energy level to the first excited state energy levels for the fundamental vibrations of the molecule, and it is for this reason that MIR spectroscopy is useful for functional group analysis. The more energetic NIR photons promote transitions from the ground state to higher than the first vibrational excited state (i.e. overtones). These photons are also capable of interacting with higher vibrational energy states of the molecule, which are combinations of the fundamental frequencies.

While the difference in energy between vibrational states is important for determining which wavelengths and in which region of the spectrum an absorption will occur, the magnitude of the light absorbed is directly related to the probability of a photon being absorbed by the molecule. If the probability is high that a given photon will be absorbed, then the absorbance measured will be high. For fundamental reasons, the probability of an NIR photon being absorbed by a molecule is far less than the probability of an MIR photon being absorbed. For this reason, to obtain a spectrum of a sample in the MIR region requires fewer molecules to interact with the light than in the NIR region. The molar absorptivity (ε) of a compound is a measure of the probability of a photon being absorbed. Molar absorptivities are generally lower in the NIR than in MIR region of the spectrum. This physical observation results in both advantages and disadvantages for these particular forms of spectroscopy which will be discussed in more detail using appropriate applications.

MIR and NIR spectroscopic techniques expose the sample to photons having a range of energies, some of which correspond exactly to the energy level transitions in the molecules of the sample. When the energy of the photon matches an energy level difference of the molecule, the photon may be absorbed, while photons having energies which do not match exactly an energy level of the molecule will not be absorbed. Thus, the energy levels of the molecule can be viewed as being probed directly when performing MIR and NIR absorption spectroscopy. The many forms of Raman spectroscopy are unique among the vibrational spectroscopic techniques in that they are not based on the absorption of a photon, but instead on the inelastic scattering of a photon by the molecules of the sample. The excitation photons used in Raman methods are not absorbed by the molecules of the sample and do not exactly match an energy level difference of the sample molecules. Instead Raman spectra are acquired by measuring the differences in energy between that of the monochromatic excitation photons and the photons scattered by the sample, this difference termed the “Raman shift” and is usually plotted in cm$^{-1}$.

The simplest way to get a feeling for Raman scattering is to invoke the presence of a “virtual” state. Unlike the energy levels of a molecule which are real, a virtual state is not a real energy state of the molecule, which means that the molecule will not exist in that state for any appreciable time. It is easiest to think of the virtual state as the energy through which the molecule passes in its transition between its initial interaction with the excitation photon and the energy that it will have at the point at which a photon is scattered. Figure 1 presents a simplified vibrational energy level diagram for a molecule having a

![Figure 1 Schematic diagrams indicating energy level transitions for Rayleigh scattering, Stokes Raman scattering and anti-Stokes Raman scattering.](#)
ground state and an excited state as well as a schematic description of the scattering processes. For this simplified example, at the time when the molecule is exposed to the incident photon, it can be in either the ground or excited vibrational energy level. If the molecule interacts with the incident photon and returns to the same energy level as it started, then the scattered photon will be of the same energy as the incident photon. This phenomenon is an “elastic” scattering process known as Rayleigh scattering. Raman scattering occurs when the initial and final energy states of the molecule are different after interacting with the incident photon. Most of the molecules of the sample will initially be in the ground vibrational energy level. Interaction with the incident photon can result in the molecule being promoted to a vibrationally excited state. The Raman scattered photon which results from this interaction will have less energy than the excitation photon, with the difference being the energy between the ground and excited states for the molecule. If the molecule in our example is initially vibrationally excited and goes to the ground vibrational state after interaction with the incident photon, then the Raman scattered photon will be of higher energy than the incident photon and thus be Raman shifted to a shorter wavelength. Since the energy difference between the excited and ground states determines the difference in energy between the incident and scattered photon, the Raman shift observed is the same for both the Stokes (Raman shifted to longer wavelength) and anti-Stokes (Raman shifted to shorter wavelength) bands. Stokes bands will, however, be more intense since there is a higher probability of the sample molecules being in the ground state when they interact with the incident photon. It should be emphasized that the overall likelihood of an incident photon being Raman scattered is very small. The vast majority of scattered photons will be Rayleigh not Raman scattered. Thus, it is critical in developing Raman instrumentation to separate the Raman scattered photons from the Rayleigh scattered photons and, in the design of the experiment, to prevent other sources of sample emission, such as fluorescence, from obscuring the weak Raman signal.

Although Raman and IR spectral data are similar in many aspects, there are many theoretical and practical differences between Raman spectroscopy and MIR (or NIR) spectroscopy. For example, the so-called selection rules, which indicate if a given transition will be active, and therefore is likely to be observed, or inactive, and therefore not likely to be observed, are different for the Raman scattering and IR absorption processes. Similarly, water, which strongly absorbs in both the MIR and NIR, is a weak Raman scatterer. Thus, water is not considered a good solvent for obtaining routine MIR spectra of dissolved analytes but is a very good solvent for obtaining Raman spectra of dissolved species. Glass, which has strong bands in the MIR region and therefore, not used for IR sampling, is a weak Raman scatterer, which is one of the reasons glass capillary tubes are often used for Raman sample holders. It is also experimentally easier to obtain Raman spectroscopic data for low-energy transitions (less than 400 cm$^{-1}$) than by IR spectroscopic techniques.

One of the experimental variables in Raman spectroscopy is the frequency of the incident photons. The intensity of Raman scattering increases in proportion to $v^4$, which is the reason that conventional Raman spectra are acquired using visible (VIS) and ultraviolet (UV) laser sources. Unfortunately, UV and VIS photons also are capable of promoting fluorescence either by the analyte or by impurities in the sample. Fluorescence is especially problematic even for the analysis of nonfluorescent analytes in real-world samples since the presence of small amounts of fluorescent impurities can provide sufficient background to obscure the photons due to the weaker Raman scattering. One approach to overcoming fluorescence induced by the incident radiation is to use lower frequency, NIR photons, which are not sufficiently energetic to promote fluorescence for most commonly encountered elements and compounds. The all important decrease in Raman scattering when using NIR incident photons is complicated further by the need to use different detectors than are used for detecting VIS and UV photons. The ability to largely overcome inherent problems with sample fluorescence experienced by conventional Raman spectroscopic techniques have justified the design and development, and has resulted in the commercial availability, of Fourier transform (FT) Raman instrumentation incorporating NIR neodymium: yttrium aluminum garnet (Nd: YAG) lasers. Owing to the higher laser powers generally utilized in FTRS and the reduced intensity of Raman scattering, it should be noted that significant advantages may be gained by using conventional, dispersive Raman spectroscopy to analyze pharmaceutical samples which do not fluoresce.

### 2 INSTRUMENTAL CONSIDERATIONS

Two distinct types of instruments are used to acquire spectral data in the MIR and NIR regions of the spectrum. To understand the difference, it is important to remember that the detectors for these regions of the spectrum are not capable of simultaneously distinguishing between different wavelengths of light. Thus one approach to acquire spectra is to separate the light into discrete wavelengths and allow only photons with a single, known wavelength to reach the detector at any time. This type of instrument often contains a grating to disperse the light, which is why they are classified as “dispersive” instruments. It
is important to note that for this type of instrument, at any given moment, most of the light from the source is not reaching the detector, is not providing information, and is, therefore, effectively wasted. Many instruments, especially those used in the NIR for process measurements, utilize optical filters, instead of gratings, to select the wavelength reaching the detector at any given time, but the same principles apply.

An alternative approach can be used for obtaining intensity versus wavelength data using a detector, which is not capable of distinguishing individual wavelengths. In this approach, all wavelengths are allowed to reach the detector at the same time; however, each wavelength in the spectral range is uniquely encoded. Thus, although the detector measures the combined intensity for all of the encoded wavelengths at a given time, suitable decoding provides information on the intensity at any given wavelength. This encoding–measuring–decoding approach is employed in the FT instruments used to obtain MIR, NIR and FT Raman spectra. The most common approach to encoding the IR light is the use of a Michelson interferometer containing a moving mirror. The light exiting from the interferometer is encoded uniquely at any given point in the mirror’s travel. An entire IR spectrum is acquired with each complete sweep of the mirror.

Several advantages which FT instruments demonstrate over dispersive instruments are often listed. The most common are the stray light advantage, the throughput advantage, and the multiplex advantage. The stray light advantage arises since only light encoded or modulated by the interferometer provides information. Stray light which is not modulated but reaches the detector does not interfere with the measurement. The throughput advantage, which practically may be more significant for an FT Raman experiment than a Fourier transform infrared (FTIR) experiment, simply stated is that more light from the source impinges on the detector at any given time compared with using a dispersive spectrometer. Clearly, at any given time in a dispersive spectrometer, only a small amount of the source radiation is allowed to reach the detector with most of the source’s radiation providing no information. The multiplex advantage is simply that all wavelengths of light are measured simultaneously when using either an FTIR or FT Raman instrument. Another advantage gained when using these types of instruments is that there is an internal laser standard which ensures the wavelength accuracy of the spectral data obtained. It should be noted that the actual importance of these and other so-called advantages for the user’s particular application must be individually assessed.

Many of the advances in vibrational spectroscopic techniques and the types of applications that are now possible are due to the vast computational capabilities, which are provided with all FT instruments and available for virtually all other vibrational spectroscopic instrumentation. Advances in computational resources (speed, memory, data storage, and display) have influenced greatly the development and expanded the areas of potential application for vibrational spectroscopic techniques over the past 20 years. In many cases, advanced spectral data-processing techniques have been used to overcome inherent instrumental limitations and difficulties in sampling, compensate for experimental variability and reduce the complexity of the spectral data obtained.

As probably expected, there is generally a high degree of similarity between most vibrational spectroscopic instruments of a given type, even among vendors. Examples of instrument layouts and components along with general descriptions of laboratory and process instrumentation can be found in most undergraduate instrumental methods of analysis texts, vibrational spectroscopy monographs, and other texts on analytical instrumentation. Rapid developments, especially advances in specific components such as optical detectors, can be incorporated very quickly in commercially available instrumentation. The value of information provided on instrument vendor websites, especially concerning current instrument design and specifications should not be underestimated.

Advances in instrumentation and computational capabilities suggest re-evaluations may be prudent for analyses deemed too difficult to perform only a few years ago.

3 SAMPLING

One of the advantages of vibrational spectroscopy is the wide variety of sampling options available. Spectroscopic data can be acquired for almost any type of sample, often with little or no sample preparation. Minimizing sample preparation is often of paramount importance, not only to reduce analysis time but also to reduce the possibility of changing the sample or introducing impurities during the process. Generally, gaseous, liquid and solid samples can be analyzed using appropriate sampling techniques. With experience, samples that are otherwise thought not to be appropriate for analysis by vibrational spectroscopic techniques, can be analyzed with the appropriate choice of sampling technique.

When choosing a sampling technique where the amount of light absorbed is to be measured (Figure 2), it is important to remember the relationship known as Beer’s law shown in Equation (1)

\[ A = -\log \left( \frac{I}{I_0} \right) = \varepsilon bc \] (1)
where \( A \) is the absorbance, \( I_o \) is the intensity of the incident light at a given wavelength, \( I \) is the intensity of light at that wavelength after passing through the sample, \( \varepsilon \) is the molar absorptivity in units of liter-moles per centimeter, \( b \) is the pathlength or thickness of the sample in centimeters and \( c \) is the concentration of the analyte in moles per liter. The molar absorptivity for a given analyte varies with wavelength and spectroscopic region. It is generally observed that molar absorptivity decreases significantly in going from the UV/VIS to the MIR and NIR regions for analytes which absorb in these regions. Thus, to acquire NIR spectra, higher analyte concentrations and longer pathlengths are generally necessary than when obtaining MIR spectra. Although this may at first seem as a disadvantage for NIR spectroscopy, it will be shown that the ability to use a longer pathlength is often considered one of the advantages of NIR for industrial applications.

The physical state of the sample often suggests the sampling technique to use. MIR spectroscopic data can be acquired for solid samples in many ways. One of the most common sampling techniques is the alkali halide or, as generally practiced, potassium bromide (KBr) pellet technique. KBr is used since it does not absorb in the MIR region and also because it cold flows when pressure is applied. Simply, the solid sample is ground to a powder, which is then mixed with spectral grade KBr powder. The mixture is placed in a special die set and sufficient pressure is applied to cause the KBr to cold flow, forming a KBr pellet, often contained in a metal collar which is part of the die set. The collar containing the pellet is placed in the instrument and an absorbance spectrum is acquired. The ratio of sample to KBr used and the thickness of the KBr pellet formed can be adjusted to obtain the desired level of analyte absorbance. Performing a quantitative analysis using the alkali halide technique can be challenging due to difficulties in preparing reproducible and representative samples.

A similar technique, often used by synthetic chemists to obtain qualitative information, is to prepare what is known as a “mull”. The solid sample is ground to a powder and dispersed in a few drops of mineral oil. This mixture is applied to a KBr or NaCl optical window and the absorbance spectrum for the mixture is obtained. Since mineral oil contains carbon–hydrogen and carbon–carbon bonds, which absorb in the mixture, regions of the spectrum containing such absorption are not utilized. To obtain spectral information for regions of the spectrum obscured by the bands of the mineral oil, a different mulling agent, generally a perfluorinated oil, is used. The perfluorinated oil absorbs in the region for carbon–carbon and carbon–fluorine bonds but provides the spectral regions not available with a mineral oil mull. Whenever preparing a mull or an alkali halide pellet, it is prudent to remember that potential chemical and/or physical changes may result from grinding the sample.

Another common way to obtain spectra of solids is attenuated total reflectance (ATR).\(^9\,^{10}\) Sampling by ATR is demonstrated diagrammatically in Figure 3. ATR sampling utilizes an optical element, which is made from a material having a high refractive index, for example zinc selenide, germanium, or diamond. Sampling is based on the principle that as light passes through a material with a high refractive index, an evanescent wave propagates at the surface of the material in contact with a medium having a lower refractive index. The evanescent wave penetrates into this lower refractive index medium for some distance. The intensity of the evanescent wave decreases exponentially with distance away from the element. If the contacting medium, which in this case is the sample, absorbs light at a particular wavelength, then a decrease in the intensity of light at this wavelength emerging from the ATR element will be observed. The depth of penetration of the evanescent wave depends on the refractive indices of the ATR element, the contacting medium (generally air or the sample) and the angle of
incidence of the light on the ATR element. The depth of penetration is wavelength dependent and generally is found to be something between a fraction of a wavelength to several wavelengths in magnitude. The number of reflections in the ATR element can be adjusted by changing the thickness of the ATR element, the length of the ATR element or the angle of incidence of the light entering the element.

Since the depth of penetration of the evanescent wave into the adjacent medium is generally small, the sample must be in intimate contact with the ATR element. Samples which are soft can be pressed on to the ATR element to achieve such contact usually without damaging the element. Care must be taken not to damage ATR elements made from soft materials when pressing hard solid samples or powders into such elements. Likewise, care must be taken not to crack and break ATR elements made from brittle materials when pressing the sample on to the surface. This is especially true when obtaining data for hard samples which are not flat. Thus, in addition to spectroscopic concerns (depth of penetration, wavelength cutoffs and regions of absorption) the type of sample also determines the material from which the ATR element is made. Since the sample is in intimate contact with the ATR element, the chemical reactivity of the sample and the ATR element must also be taken into account.

Another sampling method for obtaining spectra of solids is diffuse reflectance (Figure 4). Diffuse reflectance spectra are obtained by directing light on to a sample and collecting the light that is reflected, diffusely, not specularly, from the sample. The amount of light at the wavelengths which the sample absorbs will be reduced in the diffusely reflected light. Thus, to obtain a spectrum, similar to an absorption spectrum, the diffusely reflected light collected from a sample is ratioed to the light diffusely reflected from a standard. Solid samples are often diluted with potassium chloride and ground to a powder, especially when obtaining a MIR spectrum. The diffuse reflectance technique is widely used for obtaining NIR spectra, often with no sample preparation required.

Spectra for liquid samples can be acquired using several sampling techniques. Transmission spectra can be acquired with the use of windows, which are transparent in the IR region of interest. The choice of the window material is made based, not only on the spectral region required for the analysis, but also on the chemical reactivity and solubility of the window material. The most common MIR transmitting materials used for this purpose are potassium bromide (KBr) and sodium chloride (NaCl). Both are water soluble, thus eliminating their use with aqueous solutions or even nonaqueous solutions containing water as an impurity. The lower wavenumber cutoff is 675 cm\(^{-1}\) and 400 cm\(^{-1}\) for NaCl and KBr respectively. Nonwater-soluble MIR windows, for example calcium fluoride and barium fluoride, are also readily available.

For nonvolatile solvents where maintaining the pathlength is not critical, spectra can be acquired by simply placing a drop of the liquid between two IR transmitting windows. Liquid cells generally use spacers to maintain a given pathlength and are often used if quantitative data are to be obtained. One concern in obtaining spectra for analytes in solution is the absorbance profile of the solvent. The primary concern is that the solvent may absorb strongly in the region of the spectrum where the analyte absorbs, thereby making it difficult if not impossible to obtain spectral information for the analyte. Water is a particularly difficult solvent for IR spectroscopy since it absorbs strongly in the MIR region of the spectrum, especially in the 1600 cm\(^{-1}\) and 3000 cm\(^{-1}\) regions of the spectrum. To obtain IR spectra of aqueous solutions, very short pathlengths (i.e. 6 µm) must be used. The choice of solvent and concentration of analyte in the sample dictates the pathlength used for the analysis. Flow cells are also available.

Liquid samples can also be analyzed using ATR techniques. Many types of ATR liquid probes are commercially available. Additionally, there are many different designs for liquid ATR cells which are available commercially, ranging from a simple-to-use trough design, where the liquid in contact with the ATR element is contained in a trough, to more elaborate ATR liquid flow cells. As mentioned above, the depth of penetration in the ATR experiment is determined by several factors, including the refractive index of the ATR element, the refractive index of the sample, which is a liquid in this case, and the angle of incidence of the light. Liquid ATR cells are normally

---

**Figure 4** Schematic diagram for typical diffuse reflectance measurement. \(I_0\) is the intensity of light impinging on the sample at a given wavelength. \(I_0\) is the intensity of light at that wavelength after being diffusely reflected by the sample.
designed such that the actual thickness of the sample in contact with the ATR element is much greater than the depth of penetration, with the only limit being the amount of sample available. Thus, ATR sampling may prove to be experimentally easier when obtaining spectra of viscous samples or samples which absorb strongly and would require, therefore, very short pathlengths to obtain useful transmission spectra.

Spectra can also be obtained for gas phase samples using appropriate sampling devices. The lower analyte concentrations of gaseous samples requires the use of much longer pathlengths than are used with liquid samples, often several centimeters to several meters. Transmission cells can be constructed from inert materials, such as glass or stainless steel with appropriately chosen IR transmitting windows positioned in the light path to allow the light to pass through the sample.

Similar sampling devices are used for acquiring MIR and NIR spectra, although the lower molar absorptivities for analytes in the NIR region lead to some differences. The lower molar absorptivities allow longer pathlengths to be used for NIR transmission experiments and, as mentioned above, diffuse reflectance spectra can usually be acquired without diluting or grinding the sample. The virtual elimination of sample preparation is a major advantage of NIR spectroscopy. Fiber optic probes are more widely used in NIR than MIR sampling.\(^{11}\)

Sampling is usually more straightforward for acquiring FT Raman spectra. The goal is to present the sample in such a way that light from the excitation laser impinges on the sample and the Raman scattered radiation is directed to the collection optics. Sampling is further simplified by the fact that glass is a weak Raman scatterer and a reasonable window material in the NIR region of the spectrum. Thus, glass nuclear magnetic resonance (NMR) tubes and melting point capillary tubes make economical sample containers for obtaining FT Raman spectra of either liquids or powdered solid samples. Caution must be exercised however in the choice of glass tube in that some glasses contain impurities or constituents that fluoresce when exposed to the NIR excitation from the laser source. An intense fluorescence background can obscure the weaker Raman bands. Another sampling concern when obtaining Raman spectra is that the sample can be degraded by the intense laser radiation. Likewise, temperature-dependent changes in the spectra may be observed due to heating of the sample by the laser. Rotating the sample so that the same spot is not constantly in the laser focus and externally cooling the sample are options for overcoming these problems. FT Raman spectra can also be acquired for solid samples with design of an appropriate sample holder. It should be noted obtaining representative spectral data for large samples may be a concern because of the small area irradiated by the laser.

4 MICROSMPLING AND MICROSCOPY

Microsampling and microscopic imaging, both IR and Raman, are areas of vibrational spectroscopy which have undergone major advances in the past 10 years. Although these techniques are often classified as being distinct from vibrational spectroscopic techniques using macroscopic sampling, it could be rationalized that these imaging techniques are simply extensions of microsampling with unique and powerful advantages. Interfacing a microscope to an IR or Raman instrument provides the opportunity to obtain spectral information for microsamples, often called microspectroscopy, and to obtain vibrational spectroscopic images.\(^{12–16}\)

The power of the microimaging techniques lies in their ability to provide spatial images for specific frequencies within the MIR wavenumber range. Since the frequencies of absorption in this range are correlated with known chemical functionalities, functionality mapping can easily be provided within the spatial resolution of the instruments. The limiting spatial resolution for IR imaging is typically in the range of 5–10 µm, which, while not high by optical imaging standards, is a limitation often overcome by the quality and quantity of spectral data obtained. The spectral resolution reported is typically 4 cm\(^{-1}\). Spectra can be acquired for samples either by transmission or reflection.

Many approaches have been taken to develop microsampling/microimaging instruments. One approach is to interface a microscope suitably modified to contain optics for the spectral region of interest with a conventional scanning FTIR instrument. This type of instrument uses a single IR detector element. Spectral data are acquired for one position of the sample at any given time. Clearly this instrumental arrangement can be utilized to obtain IR spectra of small samples, which is really better termed microspectroscopy rather than imaging. To obtain an IR image of a sample, the sample stage is moved a precise distance between data acquisition for adjacent points.\(^{13}\) The scientific literature contains many elegant studies performed using this rather mechanical approach to IR imaging, which although time-consuming has been practiced for many years and is representative of most of the IR microscopic imaging systems in use today. Recently, IR array detectors have become available. The availability of these detectors is likely to revolutionize the use of IR imaging in the laboratory, assuming the cost for these instruments eventually reaches a level which makes them available to reasonably well equipped laboratories.
One recent development in IR microscopic imaging systems is the combination of a step scan FTIR instrument with a suitably modified microscope containing IR optics and an IR array detector, typically a 64 × 64 array of mercury cadmium telluride (MCT) elements. To understand how this instrument obtains IR spectra, it is necessary to review how a conventional scanning FTIR works. When using a continuously scanning interferometer and a single detector, as is common in laboratory instruments, with or without a microscope attachment, a complete IR spectrum is obtained each time the moving mirror of the interferometer makes a complete scan. The detector simply measures the intensity of the IR radiation falling on it at discrete times (i.e. distances moved by the mirror) as the mirror makes a continuous scan. This approach works well for a single detector element, but does not work if the data acquired from multiple elements (i.e. 4096 elements in a single detector element, but does not work if the data makes a continuous scan. This approach works well for times (i.e. distances moved by the mirror) as the mirror intensity of the IR radiation falling on it at discrete times (i.e. distances moved by the mirror) as the mirror makes a continuous scan. This approach works well for a single detector element, but does not work if the data acquired from multiple elements (i.e. 4096 elements in a 64 × 64 MCT array) must be acquired and saved before moving on to the next data acquisition position of the mirror. To overcome this problem, the interferometer is changed from one that acquires data by making a continuous scan to one that has a mirror which stops and acquires data for each appropriate position in the mirror travel. Thus, although each full scan produces a complete interferogram, each point of the interferogram is acquired by stopping the mirror, collecting the IR intensity impinging on each element of the array, and saving these data before proceeding to the next mirror position where the process is repeated. Clearly advances in this instrumentation are likely to be made as larger, faster detector arrays and associated electronics become available in the future.

Applications and issues in microspectroscopy, with special emphasis placed on determining the types of particles of particular interest to people working with pharmaceuticals have been covered extensively by Aldrich and Smith. They provide an appendix listing many sources of particulates commonly found in pharmaceuticals. They also describe general approaches, methods and problems encountered in identifying particulate matter and show how IR microspectroscopy can provide information which complements or confirms the information obtained using other techniques. Applications of IR microimaging in several fields, including minerals, biological materials and semiconductor materials have been reviewed by Krishnan et al. and others. While not applications of pharmaceuticals directly, the examples provided demonstrate the broad applicability of the technique. Owing to the recent developments in array technology and the limited availability and high cost of the latest versions of the FTIR imaging instruments, references to their use for solving pharmaceutical problems are limited. Still it is not hard to imagine, based on the applications already in the literature, that the impact of this new technology and likely improvements in hardware, software, and pricing will result in the use of such systems for solving pharmaceutical problems. An interesting hybrid sampling technique which has recently become available combines the features of ATR and microscopy. Using this technique the sample being analyzed is visually imaged through the ATR element, thus allowing the scientist to see the region being sampled by the element. This micro-ATR sampling technique, using a diamond-tipped ATR element, has been reviewed by Coates and Reffner. As pointed out by these authors, the development of FTIR instruments has greatly increased the opportunity for using sampling techniques where energy throughput considerations were limiting for the older dispersive IR instruments, such as ATR and microsampling applications. Another development has been the introduction of diamond surface ATR elements. Clearly, the use of diamond in addition to providing mechanical advantages also provides more chemical compatibility than many of the other high-refractive-index materials commonly used as ATR elements. (MIR diamond ATR devices are available and have been used for process analysis applications.)

Owing to the high cost of diamond, diamond-tipped ATR elements have been used for microsampling. For these devices, the area sampled is approximately 1–2 mm in diameter. The light absorbed by the diamond could interfere with an analysis, but this effect is limited by the small pathlength of diamond through which the IR light must travel owing to the limited thickness of the diamond coating and the limited number of ATR reflections (i.e. 1) in the diamond material.

The ability to visually observe the area being sampled by viewing through the ATR element clearly has merit. A sampling device employing a diamond, micro-ATR element and a charge-coupled device camera which allows such sample viewing has been developed and has recently become commercially available. Coates and Reffner present several applications as examples of sampling using this device, including the analysis of ink printed on a business card, the analysis of several layers of a fiber-optic cable, and the analysis of hair. This approach to IR sampling may prove to be a practical and possibly lower-cost alternative to IR microscopy for routine analysis of at least some types of samples.

5 APPLICATIONS

5.1 Mid-infrared

Pharmaceutical applications of MIR spectroscopy have been published for decades, but the commercial availability of lower-cost FTIR instruments has greatly increased
the range of applications and data processing possible. One area of application which has received a great deal of attention in the literature is the analysis of polymorphs. Several selected examples of polymorph analysis are presented here. For additional references and background the reader is directed to one of the several excellent reviews published.\textsuperscript{[19,20]}

Hartauer et al.\textsuperscript{[21]} described the quantitative analysis of polymorphs of the antibiotic sulfamethoxazole with diffuse reflectance FTIR utilizing the partial least squares (PLS) method for data analysis. The use of diffuse reflectance instead of the KBr pellet or mull techniques is highlighted because of advances in the signal-to-noise ratio obtained with commercially available diffuse reflectance infrared Fourier transform (DRIFT) accessories. Data are collected for light, which is diffusely, not specularly reflected, by the material of interest, which is usually dispersed in a nonabsorbing matrix such as potassium chloride. The authors point out that to obtain quantitative information from the reflectance data obtained, the Kubelka–Munk relationship is employed. This relationship produces a linear relationship between the Kubelka–Munk intensity and the concentration of scattering species, although there are several assumptions inherent in the use of this relationship. The scattering coefficient for the material of interest must be constant, and the light reaching the detector must be diffusely, not specularly, reflected from the sample. As emphasized by the authors, there are several experimental variables which need to be monitored to control the amount of specularly reflected light and the scattering coefficient of the material. Among these variables are some which can be controlled by sample preparation, including the particle size of the scattering material, the packing density, and the homogeneity of the sample, as well as the optical design of the diffuse reflectance accessory used. Fitting the overlapping peaks of the spectra obtained for appropriate calibration standards using the PLS regression approach allowed the concentration of each polymorphic form in an unknown sample to be calculated. For calibration, pure samples of the two sulfamethoxazole polymorphs were prepared and characterized. Sample preparation included grinding the samples to obtain a more homogeneous particle size, although sieving would have been employed if grinding was found to affect the polymorphs. The ground samples were then vigorously mixed with micronized KCI powder, which had a particle size of 1–10 µm. The mixed powder was then placed in a sample cup and compacted using a 2-kg weight. The importance of using a reproducible sample method was stressed. It was noted that significantly sharper spectral bands were obtained for the polymorph which had been ground. Experiments were performed to check the linearity of the Kubelka–Munk intensity with concentration. At lower concentrations of the polymorphs (i.e. less than 2% in KCl) good linearity was observed for several of the less intense bands of each of the polymorphs, but the authors caution that intense bands in the spectra do not demonstrate such linearity, possibly because of increases in specular reflection with increased absorptivity at a given wavelength. Using PLS methods to analyze the data for several calibration standards provided average absolute errors between the actual and predicted values of 0.006% and 0.004% for the two polymorphs of sulfamethoxazole, given as a percentage of the each of the polymorphs in KCl.

Previously, Deeley et al.\textsuperscript{[22]} compared FTRS with NIR excitation to FTIR spectroscopy for analyzing binary mixtures containing two of the five polymorphs of cortisone acetate. The polymorphs of this compound are known to be insensitive to grinding, thus grinding can be used to prepare homogeneous mixtures of the polymorph standards. Both FT Raman and FTIR spectra were recorded for this study using the same optical bench. One potential advantage of FTRS is that no sample preparation is required for powdered samples, although often minimal sample preparation is required for diffuse reflection FTIR measurements. One of the concerns in Raman spectroscopy is the amount of excitation laser power to use for the measurement. Increasing the excitation power of the laser increases the Raman scattering of the sample, but also may thermally damage the sample or increase the number of photons due to fluorescence by the sample or impurities. For this study, excitation powers ranging from 125 to 250 mW mm\textsuperscript{-2} were used. It should be noted that since the intensity of Raman scattered radiation from a sample is dependent on excitation power and the Raman experiment is generally performed as a single-beam experiment (i.e. no ratio performed to correct for source fluctuations), the laser power must be constant for quantitative studies. The authors also state that the degree of spectral difference for the polymorphs of most compounds is similar when comparing FT Raman and FTIR spectra. The exception is that the IR spectra of polymorphs involving hydrogen bonding tend to show larger differences than those observed in their Raman spectra. Spectra were analyzed using a commercially available modified principle components regression analysis package. Experimental characterization of two of the polymorphs of cortisone acetate by FTRS was reported with standard errors of prediction of less than 2.5% in some cases, showing that in some cases this technique is a reasonable alternative to FTIR for characterizing polymorphs.

Salari and Young\textsuperscript{[23]} used FTIR/ATR to identify and quantify the three polymorphs of a model compound, ganciclovir, in mixtures. They point out that the use of ATR for analyzing polymorphs in pharmaceuticals was suggested by Higuchi et al.\textsuperscript{[24]} in 1969. ATR spectra can be acquired quickly, with little or no sample
preparation required, and this sampling technique is nondestructive. Samples are generally not subjected to excessive pressures, in contrast to the pressures used to prepare KBr pellets to obtain transmission spectra. Experiments were performed to determine the concentrations of the three known polymorphs of the antiviral, ganciclovir. The polymorphs have distinctive spectra in the region between 1800 cm\(^{-1}\) and 600 cm\(^{-1}\). The calibration set included the pure polymorphs along with binary and ternary mixtures prepared from the pure polymorphs.

ATR spectra were acquired with the use of a commercially available, 9-bounce diamond horizontal ATR accessory. Limited pressure was applied to maintain contact between the sample and the diamond ATR element. The PLS algorithm was used for quantitation. The mean absolute errors between actual and predicted concentrations of the polymorphs in the mixtures for one of the validation sets ranged from approximately 3 to 6 w% and were polymorph dependent.

Crystals of famotidine, an \(\mathrm{H}_2\)-receptor antagonist, have been studied by several researchers using several spectroscopic methods, including FTIR.\(^{(25,26)}\) The solubility and therefore the bioavailability of the different polymorphs of a drug may be different, which is one of the reasons necessitating the efforts to identify and characterize them. Hagedus et al.\(^{(25)}\) studied two polymorphs of the drug crystallized from water. To prepare one form, the water was allowed to cool very slowly while the second form was prepared by pouring the aqueous solution over ice. FTIR spectra were recorded at 1 cm\(^{-1}\) resolution for the crystals dispersed in KBr and pelletized. Spectra for the two polymorphs obtained are clearly different. Using the absorption band at 3506 cm\(^{-1}\), it was estimated that the presence of between 1% and 2% of the crystal form prepared by the rapid cooling method could be determined in a mixture being primarily the crystal form obtained by slowly cooling the aqueous solution.

Hassan et al.\(^{(26)}\) prepared and characterized three polymorphic forms of famotidine which were determined to be present in crystals prepared from several solvents and mixtures of solvents. The “A” form was crystallized slowly from acetonitrile. The “B” form was crystallized from methanol and mixtures of water–methanol, methanol–diethyl ether, acetonitrile–diethyl ether, tetrahydrofuran–diethyl ether, tetrahydrofuran–n-hexane, methanol–benzene and methanol–toluene. The “C” form was prepared by dissolving the famotidine in boiling tetrahydrofuran followed by filtering and adding diethyl ether so that the crystals formed in a tetrahydrofuran–diethyl ether solution. Transmission IR spectra were acquired for the crystals prepared as KBr pellets. It was noted that grinding and the pressure required to prepare the KBr pellets did not affect the polymorphic form of the compound. Significant differences were observed in the spectra of the A crystal form, which was prepared from acetonitrile and crystals obtained from tetrahydrofuran–ether or methanol. A distinct peak at 1672 cm\(^{-1}\) was observed for the crystal form obtained from acetonitrile. A similar absorption was observed by Hegedus et al.\(^{(25)}\) for one of the polymorphs that they had characterized. Likewise, both groups observed a peak at 3506 cm\(^{-1}\) in one of the crystal forms. Other spectra observed for the two other crystal forms were also highlighted.

An idea of the range of applications of MIR spectroscopy can be seen in the following examples. Wasacz et al.\(^{(27)}\) described the use of MIR diffuse reflectance data to determine the hydration state of pharmaceuticals, specifically a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor. They described the spectral differences that are observed when spectra are taken for the sample incorporated into a KBr pellet or taken by diffuse reflectance without use of a halide diluent. Diffuse reflectance data were acquired at several temperatures, from 25 to 185 °C for samples which had been exposed to different atmospheric humidity conditions. They monitored the spectral features for adsorbed water and water of hydration which is incorporated into the crystal. Also monitored were changes in the OH stretching region for magnesium stearate, a compound commonly used in pharmaceutical formulations, which exists in anhydrous and several hydrated forms. Differences observed in the OH stretching region for spectra acquired by the variable temperature DRIFT technique allowed the characterization of both the di- and trihydrated forms of this compound. Their conclusion was that using variable temperature DRIFT spectroscopy and exposing the compound to different humidity conditions provided “unambiguous characterization of the pharmaceutical hydrates”.

Several papers have reported using FTIR spectroscopy to monitor interactions between pharmaceutical compounds and carriers. Hirasawa et al.\(^{(28)}\) described using FTIR spectroscopy to characterize interactions between naproxen and lactose, which was used as the carrier for the solid dispersion. Samples were prepared by mixing various proportions of the drug, heating to 220 °C, which is the melting point of lactose, stirring the resulting melt to provide a homogeneous mixture, and then rapidly cooling to solidify. FTIR spectra were acquired for the solid samples as KBr pellets. Monitoring the bands in the carbonyl region for crystalline naproxen, and both physical mixtures and solid dispersions of naproxen and lactose provided information on the type of interactions which occur for the drug in the solid dispersion. The spectra of the carbonyl region for these samples provided information on the presence of the free carboxylic
group, a dimeric structure and a hydrogen bonding interaction between the lactose and naproxen. In the solid dispersions, the degree of hydrogen bonding between the lactose and the drug was found to be dependent on the carrier/drug ratio.

FTIR spectroscopy has also been used to monitor changes in the matrix of polymer-based, controlled-release delivery systems. It has been used as part of a study to characterize degradable poly(lactide-co-glycolide) (PLGA) films employed to deliver tetracycline. Of particular interest for this study was the effect of incorporating a soluble salt, sodium chloride, at different loadings into the polymeric system. Drug release studies were performed by placing the tetracycline containing film samples in phosphate-buffered saline and held at 37°C for up to 42 days. Samples of the films were taken at predetermined times and lyophilized. FTIR spectra of cast films of these samples were acquired up to the 21-day time point. Peaks which are characteristic for lactic acid, glycolic acid, and PLGA observed in the 1400–1500 cm⁻¹ region were monitored over time. While no change in the peak intensities was observed during the first day of immersion, for samples removed in subsequent days the intensity of the glycolic acid and PLGA peaks decreased relative to the lactic acid peak. These changes in relative peak intensity with time were interpreted to indicate a difference in the rate of degradation between the glycolic acid components and the lactic acid components of the polymer. Spectral differences were also noted in the 1000–1300 cm⁻¹ region for samples with and without sodium chloride incorporated into the polymer. These differences were interpreted to indicate that the salt containing samples were more crystalline.

FTIR, X-ray diffraction (XRD) and thermal analysis were used to characterize formulations of the calcium channel blocker, nifedipine, in binary systems with the phospholipids, dipalmitoylphosphatidylcholine (DPPC) or dimyristoylphosphatidylcholine (DMPC). It is been shown that the dissolution and absorption of drugs which are very sparingly soluble in water can be improved by formulating with small amounts of a phospholipid, such as DPPC or DMPC. The study included physical mixtures, solid dispersions and ground mixtures of nifedipine and phospholipid at approximately 9:1 w/w ratios. FTIR data were acquired for these samples as KBr pellets. The authors concluded, based on the FTIR spectra obtained, that preparing the nifedipine–phospholipid mixtures by either grinding or coprecipitation resulted in no molecular or crystal structure changes.

The ability of specific compounds to enhance the transdermal delivery of drugs has been investigated on humans, in vivo, using ATR coupled with FTIR. Oleic acid is known to be a skin permeation enhancer. Such compounds reduce the skin barrier function, which has been correlated with increased transepidermal water loss (TEWL). Studies were performed exposing the patches of skin on the arms of the volunteers with test solutions of mixtures of oleic acid and propylene glycol. Both TEWL and ATR/FTIR measurements were performed. The FTIR measurements were made by placing a ZnSe ATR element directly in contact with the skin. The area of skin sampled was 7 cm².

The IR absorption bands in the carbon–hydrogen stretching region (~3000 cm⁻¹) and the carbonyl region (~1720 cm⁻¹) were monitored to ascertain the location and effect of oleic acid on the skin. The position and bandwidth of the methylene asymmetric stretches of the stratum corneum lipids provided an indication of the perturbing effect that the oleic acid has on the stratum corneum lipid barrier. The greater the perturbation, the larger the shift of the methylene asymmetric stretching frequency to higher wavenumber. Carbonyl bands at 1740 cm⁻¹ and 1710 cm⁻¹ were used as indicators of the esterified carbonyl group of the esterified lipids and the free carbonyl group of the oleic acid, respectively. Monitoring the absorbance of the free carboxylic acid group provided an indication of the movement of the oleic acid from the surface either by diffusing deeper in the skin or spreading laterally through the skin. Changes in the 1710 cm⁻¹/1740 cm⁻¹ absorbance ratio over time could also possibly indicate esterification of the oleic acid functional group.

An interesting application of FTIR/ATR of interest for pharmaceuticals is the determination of diffusion coefficients for liquids in anhydrous lanolin and poly(ethylene glycol) (PEG) ointment. The diffusion coefficients were determined for several test liquids, including pyridine, acetophenone, methyl salicylate, and 4-chloro-4′-fluorobutyrophenone. A horizontal ATR cell with a 45° angle of incidence ZnSe ATR element was used for these measurements. The experiments were performed by placing a layer of lanolin or PEG ointment on the ATR element. The layer was contained in a template prepared by punching a hole in a 0.157 mm-thick sheet of Teflon®. The thickness of the layer was limited to the thickness of the template by scraping off any excess with a razor blade. A bead of the same material was placed around the hole and served as a liquid barrier. The diffusion coefficients were determined by placing 20-µL aliquots of the test solution in the well formed, and acquiring IR spectra over time as the compounds diffused into the layer. The depth of penetration of the IR beam into the layer was estimated to be from 0.6 to 0.9 μm. As the concentration of the liquid within this depth of penetration increased with time due to diffusion, the magnitude of the absorbance of the characteristic peaks for the liquid increased. The increase in absorbance was monitored over time with these data used to calculate the diffusion.
coefficients for the test liquids. The diffusion coefficients measured ranged from $0.56 \times 10^{-7}$ to $7.2 \times 10^{-7}$ cm$^2$s$^{-1}$.

Many studies have shown that particle size is an important variable that must be controlled to obtain quantitative results from diffuse reflectance FTIR measurements. Otsuka and Matsuda exploited the relationship between intensity of light absorbed and particle size, as derived by Duyckaerts, to measure the particle size of phenytoin in pharmaceutical preparations. Diffuse reflectance spectra were obtained for the phenytoin powders dispersed in micronized KBr powder at 0.5%. The reflectance spectra obtained were corrected using the Kubelka–Munk relationship. The intensity of the phenytoin absorption at 1724 cm$^{-1}$ was measured after correcting the baseline in that region. A linear relationship was found between the absorbance at 1724 cm$^{-1}$ and the reciprocal of the mean particle size, both for pure phenytoin and a binary mixture of phenytoin and lactose.

One of the strengths of MIR and NIR spectroscopy is the ability to analyze solid samples directly. Solid dosage forms of benzodiazepines were studied by reflectance spectroscopy by Ficarra et al. These studies were performed using a dispersive IR spectrometer operating at 8.5 cm$^{-1}$ resolution at 2000 cm$^{-1}$. Samples were mixed with KBr powder in proportions of 1:10 w/w. Plots of the Kubelka–Munk transformed reflectance data versus wavenumber were produced for several pure benzodiazepines. Diazepam in both laboratory-prepared excipient mixtures used to simulate the commercial drug product and commercially available capsules were analyzed using the same sample preparation procedures. The results presented indicate that using this method the concentration of diazepam in drug product can be determined with a high degree of confidence.

The use of NIR and MIR diffuse reflectance spectroscopy to verify the identity and content of drug formulations in both capsules and tablets was investigated. The goal of the study was to develop a method for routine identity testing for clinical packaging. Requirements included that the method be rapid and could be applied by minimally skilled technicians. Formulations containing simvastatin, enalapril maleate, lovastatin and finastride were employed in this study. Distinguishing between lovastatin and simvastatin, which differ only by an $\alpha$ methyl group of an ester carbonyl, was taken as a difficult identification problem. The MIR region was found to be capable of providing such discrimination, while NIR spectra were not able to provide as clear discrimination at low concentrations. Sample treatment included milling the capsules and tablets with a grinding mill. A grinding time in excess of 5 min was found to affect the quantitation but not drug identification. A resolution of 8 cm$^{-1}$ was determined to be sufficient for this analysis. For tablets and capsules containing 0.2–40 mg of drug, the method was capable of determining 1% (w/w) of drug in the specific formulations tested.

Proteins of pharmaceutical interest have also been the subject of MIR studies. ATR/FTIR was used to study silk fibrogen gel, which was being investigated as a new oral dosage form for elderly patients. Silk fibrogen is a protein which is harmless to humans, has unique properties, and provides a dosage form with a jelly-like consistency, which makes it easier to swallow. Spectra were acquired for the silk fibrogen in solution and as a gel by ATR using a germanium ATR element. Changes in the structure of the protein from random coil to $\beta$-structure as the protein gels were determined by monitoring the amide I and amide II bands of the protein between about 1650 cm$^{-1}$ and 1520 cm$^{-1}$.

Carpenter et al. reviewed the use of MIR spectroscopy for monitoring the secondary structure of proteins to establish formulations which provide stable lyophilized products. It is known that some excipients can prevent proteins from denaturing during the freeze-drying process. Using IR spectroscopy, the secondary structure of the protein can be monitored in aqueous solution, the frozen sample and as a freeze-dried solid. Comparison of the secondary structure, especially the degree of unfolding of the protein, is indicative of the stability of the freeze-dried product. The positions of the amide I bands of the protein, which occur in the 1700–1600 cm$^{-1}$ region, are sensitive to the secondary structure of the protein. Monitoring changes in the band intensity and position provides information on changes in the native state of the protein in going from the protein in aqueous solution to the lyophilized solid. The effect of excipients, such as sucrose, on the stability of the protein can thus be evaluated. Obtaining the IR spectra for aqueous solutions containing several milligrams per milliliter is reasonably straightforward with the use of appropriate, short-pathlength sample cells and modern FTIR instruments. Spectral data processing, however, can be somewhat involved since the amide I bands of the protein overlap the strong water absorption band in this region. Spectral subtraction is performed to remove the water contribution from the spectrum of the protein in solution. The amide I bands of the protein are broad and overlapping, but taking the second derivative of the resulting spectrum assists in determining the positions of the individual amide I bands of the protein. The positions of these bands are indicative of the presence of the various secondary structures (i.e. $\alpha$-helix, $\beta$-sheet, unordered) present in the protein.

Often FTIR instruments are coupled with other instrumentation resulting in a powerful analytical tool for a specific type of analysis. Rodriguez and Bugay combined a thermogravimetric instrument with an FTIR instrument using a commercially available interface to
determine the identity of the compounds volatilized from a sample upon heating. The evolved gases were carried using helium into a multipass gas cell which was held at 160°C. FTIR spectra were acquired at a rate of 1 min\(^{-1}\) at a spectral resolution of 4 cm\(^{-1}\) as the samples were heated from ambient temperature to 300°C at a rate of 10°C min\(^{-1}\). The availability of spectral libraries of vapor phase species simplifies compound identification. Experiments can be performed on a little as 1 mg of sample and analysis times are short. Basically, the experiment follows the weight loss of the material as the temperature increases and correlates changes observed in the spectrum of the gas in the spectroscopic cell with changes in the sample’s mass.

Studies were conducted to determine the form of several solvates and provide information on the presence of residual solvates for several pharmaceutical compounds. One example presented shows how the authors used the combined thermogravimetric analysis (TGA)/FTIR technique to determine that a butyl acetate solvate was formed in a 1:1 mole ratio for a compound under investigation for the treatment of hypercholesterolemia. The authors show that TGA/FTIR, when used in combination with other techniques such as differential scanning calorimetry (DSC) and XRD, provides a powerful tool for studying solid pharmaceuticals.

Photoacoustic (PA) spectroscopy is another hybrid spectroscopic technique which, although not as widely utilized as the other sampling techniques discussed, may provide unique advantages for some pharmacologically important sample types.\(^{6}\) The FTIR/PA spectroscopy experiment is based on the principle that when a sample absorbs light, a portion of the energy absorbed is dissipated as heat. If light is absorbed close to the surface of the sample, the temperature of the surface and the atmosphere immediately surrounding the sample will increase. Modulating the source of the light results in a modulation of the surface temperature, and likewise the temperature of the surrounding atmosphere, resulting in the formation of an acoustic wave which can be detected using a microphone. PA spectra have been acquired using both dispersive IR and FTIR instruments. The use of FTIR instruments employing step-scan, rather than continuously scanned, interferometers for PA applications has been of recent interest.\(^{41,42}\)

Neubert et al.\(^{43}\) used FTIR/PA spectroscopy to determine the concentration of the drugs dithranol and brivudin in a petroleum jelly formulation. To determine the concentration of active ingredient in such formulations often requires the use of a separation technique such as high-performance liquid chromatography (HPLC) or capillary zone electrophoresis (CZE) to physically separate the active ingredients from the matrix prior to quantitation. Spectroscopic techniques can eliminate the need for employing a physical method of separation, with the minimal sample preparation required for the PA technique being a major advantage. Using bands between 1545 cm\(^{-1}\) and 1770 cm\(^{-1}\) for brivudin and between 1560 cm\(^{-1}\) and 1670 cm\(^{-1}\) for dithranol a good correlation was found between the concentrations determined by HPLC and by PA spectroscopy for samples ranging in concentration between 1.0 and 10.0 wt% dithranol in petroleum jelly and for CZE and PA spectroscopy between 0.5 and 10.0 wt% brivudin in petroleum jelly. The integrated intensities for the bands of dithranol and brivudin were ratioed to the intensity of a band due to the petroleum jelly. The data were acquired using a step-scan interferometer with a total scan time of approximately 21 min. The PA spectra were acquired at a resolution of 12 cm\(^{-1}\) and were normalized by ratioing to a spectrum of carbon black.

One area which has potential for being utilized more for pharmaceutical applications is vibrational optical activity (VOA). Though VOA includes both Raman optical activity and the corresponding IR version, vibrational circular dichroism (VCD), recent developments are the reason for concentrating on VCD here.\(^{2,44}\) VCD can be used to obtain information on the optical purity of a mixture of enantiomers, help determine the absolute configuration of a molecule or provide conformational information.

The basis for VCD is that optically active molecules interact differently with right circularly polarized light than left circularly polarized light. One of the enantiomers of a molecule may, for example, absorb more right circularly polarized light, than left circularly polarized light at the same wavelength. A VCD instrument is designed to measure the difference between the amount of light absorbed for the two polarizations at a given wavenumber, or \(\Delta A\). The VCD spectrum is a plot of \(\Delta A\) vs wavenumber.

The magnitude of \(\Delta A\) is very small, approximately \(5 \times 10^{-4}\) times the magnitude of the absorbance.\(^{2}\) Measuring such a small difference between the amount of light absorbed for the different polarizations makes the measuring of a VCD spectrum instrumentally challenging. Both dispersive and FTIR-based VCD instruments have been assembled. The modification of either instrument to acquire VCD spectra involves passing alternately left and right polarized light through the sample and measuring the difference in the amount of light absorbed. To produce the left and right circularly polarized light, two polarizers are placed in the optical train prior to the sample. First, unpolarized light produced by the IR source is linearly polarized by passing through a wire grid polarizer. This linearly polarized IR light then is converted to either right or left circularly polarized
light using a photoelastic modulator (PEM). The PEM is operated so as to alternately produce right and left circularly polarized light.

VCD, in addition to providing information on absolute configuration of an optically active compound is also capable of providing information on the conformation of such a compound in different environments. For example, Nafie and Freedman discuss the use of VCD for studying the conformation of the antiarrhythmic drug, (S)-propranolol, in solution. The recent introduction of a commercial, dedicated, FTIR-based, VCD instrument has the potential to increase the use and importance of VCD for pharmaceutical applications in the future.

5.2 Near-infrared Spectroscopy

One of the best places to get started for anyone interested in NIR spectroscopy is the many reviews on NIR applications in the pharmaceutical industry. NIR spectroscopy has been employed for the analysis of pharmaceuticals for over 30 years. The history of the application of NIR to pharmaceuticals has been reviewed by Kirsch and Drennen. The review also discusses briefly the many chemometric methods which have been applied to NIR spectra and reviews the application of NIR of solid dosage formulations and intact dosage forms. In order to obtain NIR spectra for solid dosage forms, the authors indicate that sample positioning is one of the most important variables in the experiment, being the “single largest source of error”. One approach to reducing this error is to acquire several spectra of a given tablet while rotating the tablet between spectral data acquisition. The average spectrum for the tablet is then computed thereby reducing the errors associated with positioning.

Corti et al. indicate that several of the advantages of NIR spectroscopy include being nondestructive, non-invasive and applicable to many sample types. Another advantage is that the lack of response of glass in the NIR region allows samples in glass containers to be analyzed. The authors also comment that the shorter wavelengths in the NIR result in more linear and reproducible calibrations for data acquired using diffuse reflectance as compared to the use of this sampling technique for obtaining MIR spectra. One of the limitations of NIR analysis mentioned is that the calibration standards must be analyzed using an independent reference method. Two of the most important aspects of the NIR analysis are the choice of the chemometric model for quantitation and determining which standards to use for calibration. Corti et al. discuss briefly the differences between the multiple linear regression (MLR) method and the full spectrum methods of principal component analysis (PCA), principal component regression (PCR) and PLS. Pretreatment of the data prior to the application of these models is also a consideration. Choosing the correct number and type of standards is also critical. Clearly the goal is to maximize the information provided by standards that are representative of the samples to be analyzed while minimizing the number of standards and time required to perform the calibration. Approaches to determining the correct standards for calibration are discussed. Several applications of NIR analyses are also discussed.

Another excellent, detailed source of information on NIR analysis of pharmaceuticals is the recent review by Blanco et al. which sites over 200 references. Many examples are provided on both quantitative and qualitative NIR analyses. Sampling and data treatment methods are also discussed. A timely section listing the websites of many Internet sources of NIR information is also provided.

Higgins provides an insightful evaluation of the use of NIR spectroscopy for industrial pharmaceutical applications. Among the points raised are that NIR spectroscopy is very useful for confirming the identity of materials and that the technique is ideal for pharmaceutical applications since the materials are generally organic and of high purity. Clearly this application is based on having high-quality raw material standard reference spectra available. The nondestructive nature of this type of analysis along with its ability to sample through many types of containers, including plastic bags, blister packages, disposable glass vials, and other packaging materials, also adds to the versatility of the technique. Liquids and powders can also be conveniently and routinely sampled. The application of NIR spectroscopy to monitoring raw materials, in-process monitoring, and postproduction monitoring, are highlighted. An example presented is the use of NIR spectroscopy to evaluate the degree of powder blending in production. In this example, the spectral response of both the active ingredient and excipients are indicative of the degree of homogeneity of the product and, thus, an indicator of the extent of blending which has taken place. Other applications mentioned include the use of NIR spectroscopy for the quantitative determination of water in freeze dried injection products, direct assays of bulk tablets and monitoring fermentation processes. One important point raised by the author, concerning the pharmaceutical applications of NIR spectroscopy, is that validated methods using NIR technology are now accepted by pharmaceutical regulators. Higgins also points out that NIR spectroscopy must eventually be accepted as a replacement for other, more traditional, methods of analysis.

Catalano discussed the implementation of NIR in the process environment. Included in the discussion were the different worlds in which the people who are involved in dealing with the process and the laboratory people
exist as well as differences in the environments in which process and laboratory instruments must operate. He also states the importance of working with a vendor in the development of process monitoring applications since the vendor should have more experience in performing such analyses under process conditions. Interestingly, Catalano stresses the importance and roles of the people involved in developing and implementing the NIR application in the process environment, especially for environments where there is no history of using such instrumentation for process applications.

Ciurczak(50) explains the development of NIR spectroscopy from the time of the discovery of this region of the electromagnetic spectrum by Hershel, through the development of the early instruments and applications of NIR to food products. Comparisons are made between MIR spectroscopy and NIR spectroscopy. What is interesting is that those factors which are often thought of as being limitations in MIR spectroscopy are exploited in NIR spectroscopy, especially for process applications. For example, MIR spectroscopy is often thought of as being an insensitive technique by analytical chemists due to the molar absorptivities being several orders of magnitude lower than those found in the UV/Vis region. The molar absorptivities in the NIR region are approximately an order of magnitude lower than those in the MIR region, which leads directly to the use of longer pathlengths for NIR measurements. The need to use longer pathlengths and/or higher concentrations, while generally thought of as a limitation in the analytical laboratory, is a benefit in process analysis. The limited sensitivity in the NIR region allows the use of larger pathlength flow-through sample “cells” which do not clog and reduce the need to dilute samples or otherwise handle the samples, as is often required when using other forms of spectroscopy. Ciurczak also briefly describes the need for mathematical data manipulation to obtain quantitative results from the NIR data acquired. Several methods and applications are mentioned. The importance of having samples and standards analyzed by a primary method available for calibration of the NIR system is also stressed.

Determining the moisture content of final drug products and components is often important. NIR spectroscopy provides a means for nondestructive analysis which requires little if any sample preparation. Zhou et al.,51 evaluated the effect of several experimental variables on the determination of the moisture content of hygroscopic drug substance at moisture levels ranging from 0.5 to 11.4% (w/w). These analyses make use of the strong water absorption bands in the NIR region (1420 and 1920 nm). Diffuse reflectance spectra were acquired from 1100 to 2500 nm for the samples in sealed glass bottles, with 16 scans being averaged for each spectrum. The reflectance spectrum for each sample was ratioed to the spectrum of a white ceramic reference. The authors chose to analyze the spectral data obtained using PLS although simple linear regression and MLR are also often employed for such analyses due to the strong water absorptions and lack of spectral interferences in these regions. The ability of PLS to remove spectral noise and model nonlinearity were given as potential reasons for using the method for this application. The results indicate that a standard error of prediction of 0.11% could be obtained in the moisture range studied for these hygroscopic samples in sealed glass containers. The use of first derivative spectra does provide a better calibration model for the 1850–1936 nm region.

Berntsson et al.,52 used NIR diffuse reflectance spectroscopy to determine the water content of hard gelatin capsules with analysis times of approximately 2 min. As in the previous example the spectra containing the strong water absorption bands were acquired in the 1100–2500 nm region. The moisture content of the capsules is important, since if it is above approximately 18% the capsules become soft, whereas below a water content of approximately 10% the capsules become brittle. Thus, the moisture content of the capsules needs to be checked before filling, which is why a fast, at-line method for moisture content evaluation is of interest. These researchers compared the results obtained using diffuse reflectance NIR spectroscopy with data obtained from loss on drying experiments. Calibration standards of the gelatin capsules were prepared by placing the gelatin capsules in chambers having known constant relative humidity for up to 20 days. A low moisture standard was also prepared by placing gelatin capsules in a chamber with desiccant for 5 days.

MLR and PLS were utilized to process the spectral data acquired. The effects of several spectral manipulations performed prior to fitting the data were also evaluated. They found that MLR using three wavelengths chosen by an iterative procedure produced the best calibration model for the data presented. Interestingly, none of the wavelengths chosen were the most intense for water absorption. All 70 wavelengths were used for calibration with PLS, which is a more robust technique than MLR and can detect outliers. The PLS weighting vectors, unlike the selected wavelengths in MLR, were found to be heavily weighted towards the regions where water absorbs strongly. Though reportedly not observed in this study, it was noted that other researchers have observed wavelength-independent changes in the spectral baseline with water absorption on silica.53 It was also noted that while empty, hard gelatin capsules were used for this study, the method should also be applicable to filled capsules, assuming appropriate calibrations standards are utilized.
Borer et al.\textsuperscript{(54)} evaluated the important sources of variability for analyses using NIR reflectance spectroscopy. The study concentrated on determining dose levels for tableted drug product samples. Several potential contributors to variability in the NIR measurement were evaluated, including the iris or aperture setting, the segment, which is a calculation variable indicating the number of data points over which the slope is calculated when converting the spectral data to a second derivative spectrum, the orientation of the sample platform, the number of scans which are averaged to obtain a spectrum, the number of samples of each tablet analyzed, the time in days over which the experiment is performed and the frequency at which a reference spectrum is acquired. The magnitude of the contribution of each of the sources of variability was evaluated. For example, the authors concluded that the segment value was a significant factor in the variability observed in the study indicating the slope should be calculated over 10 points. The orientation was important for embossed samples, while the number of scans was not an important source of variability. The effects of other potential sources of variability, including lot-to-lot variations in the tablets, inhomogeneity within a lot of tablets, and temperature were not evaluated in this study. The study shows the importance of evaluating the magnitude of the contribution of each of the many potential sources of variability in NIR and other spectroscopic analyses.

Comparisons between different data acquisition methods, types of NIR instruments and data manipulations for quantitative analyses of solid pharmaceutical samples was evaluated by Dreassi et al.\textsuperscript{(55)} Experiments were performed using two NIR instruments, one an FT NIR instrument and the other a dispersive NIR instrument. The methods of sampling compared included direct diffuse reflectance measurements of the samples and sampling using a fiber optic probe. The PLS algorithm was employed for quantitation. Samples analyzed included powders containing benzydamine hydrochloride and tricetol, as well as ibuprofen and paracetamol as pills or tablets. Quantitation based on the second derivative spectra were found to provide the best calibration. The authors comment that using higher derivative spectra reduces the effects of particle size on the reflectance data obtained, thereby improving calibrations for samples having a distribution of particle sizes.

Wargo and Drennen\textsuperscript{(56)} used diffuse reflectance NIR spectroscopy to characterize the degree of homogeneity of powder blends. Blend homogeneity is an important consideration in preparing drug product and is typically measured prior to tableting or encapsulation. The homogeneity of blends of hydrochlorothiazide, fast-flow lactose, croscarmelllose sodium and magnesium stearate were investigated in this study. Data were acquired using a dispersive NIR instrument by collecting spectra from 1200 to 2400 nm sampling directly through the bottom of the borosilicate sample vials. The homogeneity of a blend is often determined by measuring the amount of the active ingredient in several samples from the same batch. If the active ingredient is found to be homogeneously distributed, the other components of the blend are also considered to be evenly distributed. Data treatment for the NIR spectra included linearization by performing a log(1/R) transformation, where R is the reflectance. The homogeneity of samples with the same component concentrations mixed for different time intervals in a twin-shell blender were assessed. The degree of homogeneity for a separate blend sampled over time was also assessed. The reflectance data obtained were evaluated to determine sample homogeneity using three methods: chi-squared analysis, the bootstrap error-adjusted single-sample technique (BEST) and the modified BEST technique. Second derivative spectra were calculated prior to performing a PCA. Chi-squared analysis is performed on individual wavelengths while the two BEST techniques utilize the entire spectrum. The results obtained indicate that NIR spectroscopy has great potential for assessing blend homogeneity as well as being a useful tool in studies designed to determine optimal mixing time and conditions.

The sampling and sample handling techniques used for acquiring spectral data is only one of the issues that must be addressed when determining an appropriate method for an analysis. The approach taken to process the spectral data is often a major concern in developing the analytical method. Often an analytical method is developed to confirm the classification of samples in a given group. One example of this type of analysis is the verification of drug lots used for clinical studies. Candolfi et al.\textsuperscript{(57)} evaluated several approaches to processing the NIR reflectance data obtained for capsules and tablets containing several concentrations of active ingredient, several excipients and for several lots. The goal was to determine which data-processing method was best for classifying the spectral data obtained. Discriminating methods were the focus of the study. A comparison was made using both parametric methods (linear discriminate analysis and quadratic discriminate analysis) and nonparametric methods (K-nearest neighbor). NIR reflectance data were acquired for the spectral region from 10000 to 4000 cm\textsuperscript{-1} for the powdered tablets and capsules using a FT/NIR instrument. The authors conclude that for clinical study lots it might be best to use a two-step approach for final classification. The first step is to discriminate between the different classes present and the second step is to use another data treatment method to positively identify the sample.
Blanco et al.\(^{(58)}\) studied the effect which the choice of calibration standards has on the quantitative results obtained for NIR diffuse reflectance analysis of both the active ingredient and major excipients of a solid pharmaceutical formulation. An optical fiber probe was used to acquire the spectroscopic data. The active ingredient for this study was oxotremorine bromide with microcrystalline cellulose, maize starch and sodium starch glycolate excipients. The importance of using standards for calibration which adequately represent the variability expected to be observed in the samples was discussed. Sources of variability between laboratory-prepared standards and standards obtained from production runs were discussed. The need for the use of a multivariate calibration method, such as PLS regression analysis, is demonstrated. The quantitative results obtained using both laboratory-prepared mixtures of the ingredients with and without additional production samples as standards are presented and discussed. The effects of calibration standards choice, spectral region used for analysis and several mathematical treatments of the spectral data, including first and second derivative spectra, were evaluated. This study clearly points out the importance of systematically evaluating how representative the standards used for quantitation are when developing a NIR diffuse reflectance method and throughout the lifetime of the application of the method developed.

Sources of variability in the NIR data were investigated systematically for tablets, and hard and soft gelatin capsules by Candolfi et al.\(^{(59)}\) Changes in both chemical and physical variables are possible sources of the spectral variability observed in such analyses. The tablets and capsules sampled contained both active ingredients, ranging from 4 to 10% in concentration, and between 4 and 10 excipients. The active ingredients were different for the various sample types. The major excipient for the tablets was lactose while the major excipient for the hard gel capsules was cellulose. The sources of error evaluated included positioning of the sample, batch-to-batch variability, interday variability and within-batch variability. The effects of spectral preprocessing methods, such as second derivatization and standard normal variate transformation on the results obtained was also evaluated. It was pointed out that while data processing and manipulation can overcome some of the variability observed in the spectral data obtained, improving the quality of the data is also important. One variable which must be controlled is the moisture content of the samples. Water absorbs strongly in the NIR region. Even if the regions of the strongest water absorption bands are avoided in interpreting the spectral data, water also affects the baseline throughout this region. Instrumental drift was also noted as problematic. These authors suggest that to improve the quality of data obtained, the NIR instrument should be located in an area where both the temperature and humidity are controlled.

The major sources of error were found by Candolfi et al. to differ for the different sample types evaluated. For example, sample positioning was found to be an important variable for both the soft and hard gelatin capsules examined. Time was also found to be a significant cause of the variation observed for these samples. One problem with analyzing gelatin capsules which could add to the variability observed is that the gelatin is sensitive to changes in humidity. For tablets, significant batch-to-batch and within-batch variability was observed which indicates a large number of representative samples which must be included in the training sets for this type of drug delivery system.

An interesting application of NIR spectroscopy assesses the degree of cross-linking of the gelatin-comprising hard gelatin capsules, soft gelatin capsules, and gelatin coatings, which is important due to their wide use in the pharmaceutical, food supplement and cosmetic industries. The degree of cross-linking affects the dissolution properties of these materials. Gold et al.\(^{(60,61)}\) have used NIR to study the effect of formaldehyde on both hard and soft gelatin capsules. In one of these studies,\(^{(60)}\) NIR spectroscopy was coupled with PCA to monitor the extent of formaldehyde-induced cross-linking in soft elastic gelatin capsules. Capsules were filled with PEG solutions (PEG 400) containing up to 0.40% formaldehyde by volume and allowed to interact for 48 h. The filling solution was then removed and the inside surfaces were thoroughly rinsed with PEG and diethyl ether. Reflectance NIR spectra were obtained for these capsules. Following a series of spectral corrections and mathematical manipulations, the resulting spectra were analyzed using PCA. Baseline shifts were observed which were attributed to changes in the water content of the capsules exposed to the formaldehyde-containing solutions since water is such a strong absorber in the NIR. Changes were, however, also observed in the absorbances at 1780 and 2200 nm which were considered to be the result of changes in gelatin cross-linking caused by the formaldehyde. These spectral changes are likely due to the effects in the NIR region of the spectrum of bonds being formed and broken during the crosslinking process.

Gold et al.\(^{(61)}\) also used NIR reflectance spectroscopy to study the effects of exposing empty, unopened, hard gelatin capsules to an atmosphere containing 150 ppb of formaldehyde for up to 24 h. After formaldehyde exposure, the capsules were filled with amoxicillin and NIR reflectance spectra obtained. The NIR data were correlated with data obtained for the dissolution of amoxicillin from the formaldehyde-treated capsules.
5.3 Fourier Transform Raman Spectroscopy

FTRS has many properties which make it attractive for pharmaceutical applications. One important property which has been exploited for biological samples is that water is a weak Raman scatterer, which means that Raman spectra can be obtained for aqueous solutions and samples which contain a high water content. Another of the complications of IR spectroscopy, the requirement that IR-transmitting materials be used for sample containers, is also diminished. Raman spectra can be acquired for samples in glass containers directly, although some care must be taken since the ingredients and impurities found in some glasses may fluoresce when exposed to the intense NIR radiation of the laser source. Probably the most important advantage which FT Raman using NIR excitation has over conventional Raman spectroscopy using UV or VIS wavelengths for excitation is that fluorescence from the sample is generally reduced. Sample fluorescence, which is generally far more intense than the Raman scattering, can result from either a fluorescent analyte or impurities in the sample. The energy of the NIR photons used for excitation in FTRS is not sufficient to result in the electronic transition required for the fluorescence of most species. One other aspect of Raman spectroscopy which is often mentioned is its complementary nature with respect to IR spectroscopy. Absorption bands which are weak in the IR spectrum of the analyte are often strong in the Raman spectrum of the material. One disadvantage of FTRS using NIR excitation, as pointed out by Spragg, is that the high-power, invisible NIR light used for sample illumination gives rise to important safety issues. For this reason, the laser, sample, optics and detector are enclosed in commercial instruments and interlocked to prevent exposure to laboratory personnel.

Petty et al. reviewed the advantages of using Raman spectroscopy, FTRS in particular, for pharmaceutical applications. Many advantages of using FTRS for analysis are noted and several examples are presented. Citing the fact that many packaging materials, again glass in particular, are poor Raman scatterers, which allows spectra to be acquired without removing the sample from its container, Spragg points out that most materials are weak absorbers of the NIR wavelength normally used for excitation in FT Raman. Obtaining Raman spectra for samples in their containers is a rather extreme demonstration that the technique requires little to no sample preparation. An example of an analysis where this property is important is a study involving the compound tegafur, which is cytotoxic. Special handling procedures are normally required when analyzing this material, but can be avoided since Raman spectra can be acquired without removing the sample from its container.

Another important advantage of Raman spectroscopy highlighted by Petty et al. is that it provides an easy means to obtain information on the low-energy vibrations occurring between 400 and 50 cm\(^{-1}\). Most FTIR instruments have a lower wavenumber limit of 400 cm\(^{-1}\), a constraint imposed by the use of KBr optical components (i.e. windows, interferometer, beamsplitter, etc.). To obtain IR spectra in the region below 400 cm\(^{-1}\), the far IR region of the spectrum, requires the use of optical components fabricated from other materials, for example CsI, which is very hygroscopic. Another complication is that water vapor absorbs strongly in the FIR region. Lattice vibrations, which may help distinguish between different polymorphs of a compound, are an example of such low-energy transitions. An example is presented for two crystal forms of an angiotensin II receptor antagonist. Distinct and characteristic differences are observed in the FT Raman spectra in the region between 50 and 425 cm\(^{-1}\) for the two crystal forms of the compound.

Hendra explained why FTRS is very often applicable to mixtures of pharmaceutical importance. Raman scattering for noncrystalline, saturated compounds composed of first-row elements is often weak compared with drugs, which are often crystalline, aromatic compounds containing elements not in the first row. Thus, although the drug may be present at lower concentrations than some of the other materials of the drug product, for example a polymer such as cellulose, the Raman scattering as a result of the drug substance may dominate the spectrum obtained. Hendra uses the example of lactose as an excipient which may, however, cause problems since it is a crystalline material and is a strong Raman scatterer. Further, if the lactose in the formulation absorbs water and becomes hydrated, the Raman spectrum of the material will vary depending on the degree of hydration. Hendra also points out that as with IR spectra, the Raman spectra obtained are dependent on the temperature of the sample. It is pointed out that both the intensity and widths of the Raman bands can change with sample temperature.

An early application of FTRS was in the study of drugs which had been dispersed in polymeric materials used in drug delivery systems. FTRS using a NIR laser for excitation is more applicable to these analyses than conventional Raman spectroscopy using VIS lasers due to the decreased interference from fluorescence when using NIR excitation and the decreased concern about photodegradation. Poly(sebacic anhydride) is given as an example of a biomedical polymer. The authors point out that by studying changes in the spectral properties of these polymers as the material is exposed to a degradation process provides for the identification of
the end products and the degree of polymer modification. For example, the end products of hydrolysis or exposure to light can be determined simply, often in situ, via FTRS. Such studies may provide information concerning the release of a drug incorporated in the polymer matrix. Analysis of FT Raman spectra of pure drug substance and drug substances dispersed in a polymer matrix provides information on the extent and type of drug–polymer interaction. For example, comparison of the spectra of the drug diclofenac, pure and as dispersed at a concentration of 20% (w/w) in sodium alginate, indicate that there is no molecular interaction between the drug and the polymer. Analysis of concentrations up to 60% (w/w) diclofenac in sodium alginate did, however, show a nonlinear, concentration-dependent intensity change for bands because of the aromatic structure of the molecule. The authors point out that using NIR excitation for FTRS may not eliminate all sample fluorescence and may present some problems for aqueous samples. In another study, Tudor et al. highlighted the use of FTRS using NIR excitation at 1064 nm provided by a Nd:YAG laser and showed spectra for several sympathomimetic amines and poly(anhydrides).

Langkilde et al. employed FTRS to characterize two polymorphs of an unnamed pharmaceutical compound. These two polymorphs are known to be stable at different temperatures and have distinct Raman spectra in the carbonyl region (bands at 1716 or 1724 cm\(^{-1}\)) due to the presence of a conjugated ester group which packs differently in the crystal structure of the two forms of the compound. According to these authors the bands are better resolved for the polymorphic forms in the FT Raman spectra than in FTIR spectra, although this may be due to sample treatment. The authors also point out that other researchers have found that polymorphs having distinct IR spectra do not have distinct Raman spectra.

A spinning-ring-type sample device was developed and used to increase the area of material sampled; thus the spectra obtained represent more closely a true average for the material present in an inhomogeneous sample. Data treatment included subtracting spectra of each of the pure polymorphs from the spectra of the mixture to determine the contribution of the other polymorph to the observed Raman intensity. For this study, it was determined that the presence of one polymorphic form in the other could be determined from about 1.8 to 15.4% of the minor form. The authors caution that one potential problem is that the absolute intensity of the Raman signal is dependent on particle size, with larger particles resulting in greater Raman intensities. Thus, particle size needs to be considered when performing such analyses, and efforts should be made to control particle size between samples and to ensure that different components in the mixture have the same particle size.

Taylor and Zografi demonstrated the use of FTRS for monitoring the crystallinity of indomethacin powders. The Raman spectra of the \(\gamma\) crystalline and amorphous indomethacin differ in the carbonyl region. Raman-scattering bands for the crystalline and amorphous forms of the compound occur at 1698 and 1680 cm\(^{-1}\), respectively, although there is some overlap due to broadening of the band for the amorphous state. To overcome errors caused by the overlap, spectra were acquired for known standards containing known ratios of the crystalline and amorphous indomethacin. Peak intensity ratios were calculated and used for calibration. Raman spectra were acquired at 4 cm\(^{-1}\) resolution using the 1064-nm line of a Nd:YAG laser for excitation. Several different experiments were performed to investigate potential sources of error. The use of intensity ratios overcomes much of the potential error associated with fluctuations in the excitation laser intensity. Although the absolute intensity of Raman scattering increases with increasing laser power, the intensity ratios measured were not found to be very sensitive to such fluctuations. One of the largest sources of error was found to be the homogeneity of mixing of the amorphous and crystalline components of the sample. The effect of particle size on Raman signal intensity also needs to be investigated. The authors, however, indicate that for indomethacin under the conditions studied, FT Raman spectroscopic analysis is capable of detecting the presence of crystalline or amorphous indomethacin to as low as the 1% level with linear calibration being obtained over the entire crystallinity range.

6 CONCLUSION

The range of applications presented show clearly that vibrational spectroscopy, especially MIR, NIR and FTRS, are well suited to analyzing samples of importance to the pharmaceutical industry. The many sampling methods available, the limited sample preparation generally required, and the nondestructive nature of the vibrational spectroscopy, are well suited to the analysis of pharmaceutical products, raw materials, and samples. Discussions with representatives of several instrument manufacturers, however, have indicated that many pharmaceutical applications of their technology, especially in the area of process control and analysis, are proprietary and not reported in the peer review literature. Thus, for some types of applications, important information should be obtained directly from the instrument designers, manufacturers, and suppliers. Instrument manufacturers’ Internet websites often prove to be excellent sources of the latest details of instrument design, at least
for that particular manufacturer, and also often pro-
vide limited information on proprietary uses for that
instrumentation. As with other types of analytical instru-
mentation, vibrational spectroscopic instrumentation is
constantly being developed and improved. Some of the
most exciting developments in vibrational spectroscopy
are the advances currently being made in vibrational
imaging. As the cost of MIR imaging instruments reaches
a point where they become more widely available,
their use in the analysis of pharmaceutically impor-
tant samples will be more readily apparent. Likewise,
continued developments in FT Raman instrumentation
and increases in general availability in industrial lab-
oratories will ensure that the unique capabilities of
this technique will be used for pharmaceutically related
applications.

The vitamins are a diverse group of compounds, both chemically and analytically, because they comprise a range of biomolecules whose common properties reside solely in the fact that they are essential dietary components, which are needed in relatively small amounts to sustain life and good health. In addition, the major analytical challenges that they present are derived from the facts that (1) there is a need to quantitate them in a wide range of biological matrices, which include both foods and body fluids (for status indices); (2) the concentrations that are present are usually very low, and the ratio to other components, which can be chemically very similar, is small; (3) they may be present in several or many chemically diverse, but biologically interconvertible, forms; (4) some of them are labile to heat, extremes of pH, degradative enzymes and so on and (5) there is no single analytical approach that can quantitate all of them together, within a biological matrix.

They have been divided, broadly, into fat- and water-soluble groups, and each of these has been further subdivided, mainly on a functional basis. Historically, the B-group vitamins were measured by various microbiological assays, and the others were measured (if at all) by semispecific colorimetric assays. Nowadays, there are several more-powerful techniques available, which include high-pressure liquid chromatography, with a range of detectors operating over a continuous range of selective modalities; radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA)-based techniques, which use specific protein-binding selectivities; enzyme reactivation techniques for certain B-vitamin status assays, and so on. The use of mass spectrometry (MS) is gaining
ground and can be combined with several other separation techniques, such as gas−liquid chromatography (GLC), capillary electrophoresis (CE) and so on. Measurement of vitamins in simple pharmaceutical mixtures (vitamin supplements etc.) is now reasonably straightforward.

The technical advances that these methodologies represent have greatly broadened the horizons of the vitamin analyst, and have permitted even some of the more difficult biological matrices to be addressed. However, the unsolved challenges of accurate vitamin analysis show little sign of receding, and there are very few, if any, laboratories worldwide that are currently able to measure all of the known vitamins in all known biological matrices. This remains a major challenge and a goal for the twenty-first century.

1 INTRODUCTION

This article describes the analytical procedures available and problems likely to be encountered for the four fat-soluble vitamins and the nine water-soluble vitamins that are that are generally recognized as being essential organic components in the human diet (Table 1). There are also other dietary organic substances which may be beneficial, or even essential under certain circumstances, but which are not currently recognized or classified as vitamins: these include several carotenoid pigments, a range of bioflavonoid polyphenols, choline, inositol, amino acids such as taurine and so on. These and other organic substances may also be essential vitamins for animals other than man, but this aspect of the subject is not included in the following account. Nevertheless, powerful separation techniques have been developed that can detect and quantitate a large number of organic components in a single analytical run. This is especially true for the carotenoids, which are frequently combined with fat-soluble vitamin A and E analyses.

Each of the vitamins comprises a small group of compounds with interrelated or interconvertible structures and biological functions. Thus chemically related compounds may perform similar functions; each vitamin is converted to several different functional forms within many living tissues and certain degradation products of these vitamins may provide useful evidence about vitamin status even though they are no longer functional. This implies that the analytical methods that are used to measure vitamin contents or status must either measure and summate all of the forms that are present, or measure a representative single form or sample of the forms that are present and then extrapolate to the sum-total of all the forms. Provided that the different forms have similar activities and that they occur in a constant ratio to each other, this is an acceptable compromise, but if this is not the case, then the problem of accurate estimation becomes more complicated. Thus the newer techniques of chemical separation and quantitation may have some disadvantages compared with the older procedures based on bioassay, but since the latter are generally difficult to automate, are usually very time-consuming and lack precision, they are, with some exceptions, steadily losing ground. Table 1 shows the synthetic form for all 13 vitamins, which would normally be used in pharmaceuticals (vitamin supplements, fortified foods etc.), and a small selection of the naturally occurring forms found in foods, blood and tissues. The latter, however, are too numerous to list exhaustively in the present review: for the folates alone, for example, the possible variations in polyglutamate chain lengths, in carbon substituents and in redox state imply several dozen biological variants. In Table 1 an indication of the relative stability of the different vitamins is included. This, too, is a complex subject because each of the different forms of the vitamins has a different stability and because the biological stability may be affected by the matrix, e.g. by protein-binding. However, it is important when planning sample collection and pretreatment procedures for subsequent analysis, to take appropriate precautions against degradation. For most of the vitamins, simple freezing at low temperature is generally adequate, but vitamin C is particularly prone to rapid oxidation, requiring extraction into a metal-chelating acid, such as metaphosphoric acid. The biological forms of folate are also prone to oxidation and will benefit from the addition of a reducing agent.

Vitamins are, by definition, micronutrients, i.e. nutrients that are present and are required in very small amounts compared with the major macronutrient components of the diet, namely the proteins, fats, polysaccharides and sugars. Indeed, nearly all of the vitamins have catalytic functions in living tissues, being recycled and reused in the biochemical pathways in which they participate, whereas the macronutrient components are continuously used up and are not recycled. This implies that the analytical challenge for the vitamins is that of a series of chemically diverse minor components within a complex matrix of major components (in foods, tissues or body fluids) and that the analytical procedures must therefore be capable of extracting them efficiently and quantitating them in the presence of large amounts of potentially interfering substances. The analytical procedures must possess an adequate combination of separation efficiency (without major losses) and analytical specificity to ensure accuracy of estimation and freedom from positive or negative interferences. In the older analytical procedures the extraction step was usually relatively crude and simple and specificity was achieved mainly by biological selectivity, e.g. by microbiological or

* Refers to the naturally occurring forms. For several of the vitamins in tissues the partial degradation of the native forms which occurs during storage of food may not affect the biopotency, even though the analytical patterns change. However, the biopotency of some vitamins is easily destroyed by prolonged storage or cooking (e.g. vitamin C) or light exposure (e.g. riboflavin, vitamin B<sub>6</sub>). animal growth assays, using growth media or feeds lacking only the vitamin being tested. More modern procedures generally include more complex extraction steps and/or cleanup and separation procedures to achieve specificity, so that the final quantification procedure can then be less specific but, as a result, is more controllable and precise. Table 2 gives an order-of-magnitude estimate of the vitamin concentrations in human blood plasma and in two types of food, and it indicates the considerable magnitude of difference in concentration between the vitamins and the major components of these typical matrices. The lower the concentration of the vitamins, the greater the analytical challenge; thus vitamins D, K and B₁₂ present an even greater challenge than the other vitamins. However, this is only part of the analytical problem, because a multiplicity of different forms (folate), poor stability (vitamin C) or a tight binding to macromolecules (several B-vitamins), all increase the analytical difficulties in addition to their low concentrations.

In the ensuing review it has not been possible to describe all of the variants of all of the analytical procedures for vitamins which have been published: this would be neither feasible within the space available, nor particularly useful, as the reader who requires such detailed information on such a wide range of alternative approaches will need to consult a range of reviews, electronic searches and/or information sources. Therefore I have focused primarily on the principles of the currently used analytical methods with some recent examples. I have also included some examples of newly developed techniques that may become better established in the future, such as CE. Analysis of pharmaceutical preparations is generally more straightforward from the viewpoint of analytical complexity than that of biological matrices; therefore this aspect has received less emphasis than the analysis of blood and urine samples (for status measurements) and of food samples (for food-monitoring and dietary analysis). Some of the older assay methods remain appropriate for laboratories in developing countries, which lack sophisticated modern analytical equipment and the means to maintain, repair and provide consumables for it. Also, dried blood spot methods are being developed for blood collection at sites where no special storage facilities are available, e.g. in developing countries.

Several volumes of the multivolume series Methods in Enzymology include a series of specific chapters on selected vitamin analysis methods, with emphasis on practical details and Ball¹¹ has extensively summarized and reviewed the methods that are available for the

analysis of vitamins in foods. There are a number of other useful reviews.\(^2-16\)

All vitamin assays require careful validation and quality control (QC). There are external quality assurance schemes (EQAS) now available for some of the vitamins, mostly for blood (status) assays, and there are also a limited number of biological materials available with assigned values for vitamins to assist with method validation. However, all analytical laboratories will also need to maintain quality assurance (QA) procedures to ensure the long-term stability of their methodologies. This is usually achieved by storing pools of relevant biological sample materials, if possible with three or four different concentrations of each analyte, covering the entire analytical range usually encountered, subdivided into small identical aliquots and stored at very low temperature to ensure long-term stability. By including these QA samples at frequent intervals throughout the course of an assay series, it is possible to assess the extent of drift and of instability in the assay procedures, including the extraction stages (which may be at least as critical as the final analytical run, since the latter is usually calibrated by pure standards). Another important precaution is to add, at as early a stage as possible, a known amount of an internal standard or standards that are similar to the endogenous vitamin(s) but are entirely absent from the sample being analyzed, and which can be quantitated in the same analytical run as the required vitamin(s). These internal standards can then be used to correct for losses during purification, provided these are not excessive. Measurement of the percentage recovery of pure added vitamin gives a further indication of the overall efficiency of the extraction procedures and controls for the presence of interfering effects of matrix components in the assay.

An even more powerful technique is to add an isotope (radioactive or stable) of the same vitamin(s) that are being measured and to use the resulting isotope-recovery information to correct for extraction- and purification-related losses. With the increasing availability of MS as an analytical tool, the use of stable isotope-labelled material as an internal recovery standard is becoming increasingly attractive. The formation of characteristic fragments by the breakdown of organic molecules during electron or chemical ionization bombardment in the mass spectrometer, promises to simplify the analytical procedure still further, by reducing the need for complete physical isolation of each organic species.

One important aspect of the analytical program which can only be touched upon in the present article is the principle by which the most appropriate sampling procedures are defined and developed. For foods, some important considerations are the choice of a representative subsample or the sampling of different portions of the entire sample so as to allow for sample heterogeneity.

For status assays a choice must often be made between whole blood, serum, plasma, washed red cells or some other cellular component of blood, or a urine sample, which may (or may not) be a timed sample, e.g. 24 h. The blood sample may (or may not) be a fasting sample. Serum, plasma or urine concentrations tend to reflect recent vitamin intakes; blood cellular concentrations usually reflect longer-term intakes and long-term status. For some vitamins, secondary or functional indices such as enzyme activities, or the extent of reactivation of partially cofactor-depleted enzymes by their specific cofactors, may be used to measure and define status, and there is a range of functional status assays that cannot be included in this article (but for which see Bates).\(^{16}\) Another important question, and a possible pitfall for the unwary, is the variety and choice of different units for reporting concentration. In the case of blood concentrations most journals now insist on SI (Système International d’Unités) (molar) units, but the older literature may also include values expressed as weight/volume, or a variety of non-standard units such as international units (IUs), which require separate definition for each vitamin. The interconversion factors for some of these are given in Table 3. In the case of food analysis the vitamins are generally expressed by weight per 100 g or weight per kilogram of fresh or cooked food. For food analysis it is also essential to define whether the food is cooked or raw, and whether or not it includes the inedible parts, such as the stones of fruit or the bones of meat and fish and so on. It may also be necessary to specify whether the concentrations are expressed on a wet or a dry weight basis. These and

other potential problems in interpreting and comparing vitamin status indices are further discussed in section 5.

2 HISTORY

During the latter half of the nineteenth and first half of the twentieth century, most of the vitamins that are now recognized as being essential dietary components were isolated, crystallized, identified and then synthesized, and the methods used were the standard organic chemistry techniques that were then available or being developed, such as solvent partitioning, fractional crystallization, paper and thin-layer chromatography (TLC), GLC and so on. For some of the vitamins, physicochemical techniques (such as fluorimetry) and the formation of chemical derivatives with characteristic absorption or fluorescent spectra, were used for the identification and analysis. With the opportune discovery that many of the vitamins (especially in the B-group) were essential for the growth of particular microorganisms in purified growth media, it became possible to select particular species and strains of microorganisms which, with defined media which lacked a particular vitamin, could be used to quantitate that vitamin in liquid samples or in tissue extracts of biological origin. Gradually a wide range of assay techniques became available, which were tailored to the analysts’ particular requirements, so that the food vitamin assay procedures then gradually diverged from those used for status assays or for pharmaceutical preparations. A brief selection of some historically important methods for the individual vitamins is listed below.

For the fat-soluble vitamins (A, E, D, K) and for vitamin C, the bioassay methods that were developed were in animals, generally based on growth stimulation in rodents such as rats or guinea pigs, or in chickens. Bioassay procedures for vitamin A, E, D, and K were of this type; that for vitamin D depended on X-ray pictures of bone growth (line test) and that for vitamin K depended on tests of the efficiency of the blood clotting process. Early procedures for the spectrophotometric assay of vitamin A in tissue extracts depended on the use of Lewis acids, such as antimony trichloride or trifluoroacetic acid, which gave a transient colored product. Vitamin E could be assayed by virtue of its ability to protect against oxidative haemolysis of red blood cells. Vitamin K status can be investigated by a variety of tests of the integrity of the blood clotting cascade which constitute specific functional tests of vitamin K status. Vitamin C was originally measured by animal assays but a number of semispecific chemical assays were also developed at an early stage, based on the powerful reductive potency of vitamin C, or the formation of fluorescent derivatives or of colored osazones, after oxidation.

Most of the B vitamins can be measured by specific microbiological assays and many of these are still in use, especially for food analysis, because they can usually cope with a multiplicity of different forms of each vitamin. However, the extraction and assay conditions require careful attention to detail and there remain some serious problems of disagreement between different laboratories about the procedures. For some of the B-vitamins, fluorimetric assays have been developed and there are protein-binding RIAs for folate and vitamin B12. Some of these have been developed for status assays, others are more suitable for foods and feeds. As clinical chemistry laboratories have developed a need for vitamin status assays, commercial kits have been developed, whose emphasis has been on simplicity, speed of use and high throughput, in contrast to the older assays, which were slow and time-consuming (but which in some cases were nevertheless more reliable than their modern counterparts).

3 FAT-SOLUBLE VITAMINS

3.1 Vitamins A, E and Carotenoids in Serum, Plasma and Breast Milk

Most clinical and epidemiological investigations of vitamin A status rely on the direct estimation of vitamin A in serum or plasma. Because many of the vitamin A assays that have been developed recently can also measure vitamins E and carotenoids, this group of analytes is generally measured in a combined assay, using high-performance liquid chromatography (HPLC) to separate the individual components and a variety of detection methods (optical density, fluorescence or electrochemical reaction: Table 4). Serum or plasma vitamin A concentrations reflect body stores only when the latter are severely depleted (liver concentration < 70 µmol kg⁻¹, plasma concentration < 0.7 µmol L⁻¹). When the liver stores are greater than 70 µmol kg⁻¹, plasma concentrations are largely independent of them. Serum or plasma concentrations that are considered to be either low (<0.7 µmol L⁻¹) or deficient (<0.35 µmol L⁻¹) occur more commonly in young children than in adults, and most commonly in poorer countries, where good dietary sources of preformed vitamin A from animal foods, or dietary supplements and of rich sources of precursor carotenoids from fruit and vegetables are unavailable. Poor maternal status can arise during pregnancy and lactation in those countries where dietary sources are inadequate, and the concentration of vitamin A in breast milk (expressed as a ratio to the fat content) may

MMA, Methyl malonic acid; PIVKA, protein induced by vitamin K absence.

be a better index of maternal intakes and status than blood levels are. Unfortunately the breast milk content varies considerably with stage of lactation, so its interpretation can be complex. Because vitamin A can be toxic at very high intakes (e.g. more than ten times the recommended intake taken regularly, or more than a hundred times the recommended intake taken intermittently), there may also be a need to investigate plasma or serum levels for evidence of overload. In this situation the concentration of retinyl esters, especially in the chylomicrons, is greatly increased so that the ratio of retinyl esters to retinol (which is normally very low), rises dramatically.

Vitamin E occurs in blood plasma or serum in a variety of different forms (reflecting the varying composition of different dietary sources), of which all-rac D-α-tocopherol is the most biologically potent (Table 3), and is usually the most prevalent form. Although modern HPLC-based (and similar) assay procedures can easily separate and quantitate each of the individual forms of the vitamin, this degree of detail is seldom necessary for the definition of normal ranges. However, it has been found to be preferable to judge status on the basis of vitamin E: lipid ratios rather than of vitamin E concentrations per unit volume, because of the strong covariance of vitamin E with lipid levels. Severe deficiency is associated with vitamin E concentrations below 1.1 μmol g⁻¹ total plasma lipid, or below 2.2 μmol mol⁻¹ cholesterol, but it has not yet proved possible to define an optimum concentration for long-term protection against peroxidative damage. Unlike vitamin A, vitamin E concentrations are not constrained by a specific binding protein and plasma levels are approximately proportional to intakes over a wide range. Overt toxicity has not been reported, even at very high intakes.

Like vitamin E, plasma carotenoid concentrations are approximately proportional to dietary intakes over a wide range; they are concentrated in the lipidic components of plasma or serum and most of them are generally considered to be nontoxic over a wide range of intakes. α- and β-Carotenes and the cryptoxanthins are partially converted to vitamin A within the intestinal wall and in other tissues, and are therefore useful contributors to vitamin A stores, especially for people whose diets do not contain animal products or dietary supplements, and therefore lack preformed vitamin A. Other dietary plant carotenoids, such as lycopene and the xanthophylls (lutein, zeaxanthin) are not precursors of vitamin A in humans, but most of the carotenoids are thought to possess useful antioxidant properties and are therefore of potential health significance with respect to the limitation of free radical-generated tissue damage. As noted earlier, they are not classified as vitamins per se, but because some of them are vitamin A precursors, because they are potentially protective, because they can provide an index of fruit and vegetable consumption and because they can be measured in conjunction with vitamin A and E, they are generally included in the assay procedures and protocols for these vitamins, especially in the context of epidemiological studies of population vitamin status.

Examples of modern assay procedures for vitamin A in serum, plasma, milk and tissues can be found in the literature. Some of these also include simultaneous procedures for vitamin E and/or the carotenoids. Other aspects of the analytical methods and status determination issues for vitamin E have been
described.\textsuperscript{(74–90)} Reviews that concentrate particularly on these vitamins are by Davidek and Velisek,\textsuperscript{(4)} De Leenheer et al.,\textsuperscript{(6)} and Furr et al.\textsuperscript{(52)} In the author's laboratory, a minor modification of method given by Thurham et al.\textsuperscript{(47)} has been in constant use for several years, and has proven to be robust, precise and accurate for the analysis of vitamins A and E and seven carotenoids in human plasma samples for survey work.

Some interesting new developments, which have not yet been widely adopted, include the use of retinoic acid as an alternative index of vitamin A status,\textsuperscript{(41)} the use of oxidation product(s) of vitamin E as an alternative index of vitamin E status,\textsuperscript{(74)} the use of CE for the separation of fat-soluble vitamins before detection\textsuperscript{(50,53,91)} and the use of MS to assist in the specific recognition of these vitamins or the use of stable isotopes for recovery assessment.\textsuperscript{(44,60,82,69,73,82,92)} Vitamin E and its oxidation products have been assayed in the cellular components (membranes) of the blood.\textsuperscript{(77,80)}

In the USA, there is an EQAS for these analytes, run by the National Institute of Standards and Technology (NIST) (Micronutrients Measurement QA Program, NIST, Gaithersburg, MD 20899, USA; fax: +1 301 977 0685; e-mail: jthomas@nist.gov). In the UK, an equivalent scheme is run by Ms Maureen Goodall, tel: +44 981 296 2804; fax: +44 181 641 2633.\textsuperscript{a}

3.2 Vitamins A, E and Carotenoids in Foods and Pharmaceuticals

The assay procedures used for these vitamins in foods overlap considerably with those used for status assays, the main differences residing in the extraction procedures, which are necessarily more complex than those needed for blood analysis, partly because the food matrix is much more variable and complex, and partly because the liberation of the free vitamins from their fatty acid esters by saponification is usually an essential part of the food analysis procedure, whereas in blood serum or plasma, most of them are present in unesterified forms.

Bioassays for these nutrients were the precursors, and in a sense the gold standards, for the later physicochemical-type assays. They bridged the gap between the functions of the vitamins, as essential components of the diet (of humans and animals) for their survival and health, and the identification of their unique chemical structures and detailed biochemical functions, which permitted the development of more sophisticated and more rapid assays, based on their physicochemical properties. For vitamin A, and for its precursor carotenoids, the carotenes and the cryptoxanthins, the animal bioassays depended on growth rate (in rats), a vaginal smear test (correction of keratinization in vaginal smears in ovariectomized rats) and a liver vitamin A accumulation or storage assay, which measured the amount of vitamin A accumulated after a predetermined dietary amount of the test food.\textsuperscript{(1)} These bioassays were able to test the relative potencies of different vitamin A precursors, but only with respect to their potencies in rats, which may differ from those in humans. Analogous bioassays have also been used for vitamin E. Three approaches that have been used successfully are the foetus resorption test in vitamin E-deficient rats, an erythrocyte peroxidative haemolysis test in deficient rats and a liver-storage test in rats or chicks.\textsuperscript{(1)}

Saponification of food homogenates before extraction is classically performed by heating with potassium hydroxide, frequently with the additional of methanol or ethanol (which helps to denature the proteins) and frequently with antioxidants such as pyrogallol, butylated hydroxytoluene (BHT) and so on. Extraction uses nonpolar solvents such as diethyl ether, hexane, tetrahydrofuran, acetonitrile and so on.

HPLC separation of vitamin A, E (multiple forms) and carotenoids in food extracts is similar, in principle, to that described in section 3.1, except that the range of components is likely to be more complex. Gradient elution with complex mixtures of solvents may be needed. Several examples\textsuperscript{(49,71,75,93–106)} may be added to those listed elsewhere.\textsuperscript{(1,4,5,11)}

The assay of vitamins A, E and carotenoids in pharmaceutical preparations is similar in principle to that in foods, but because the concentrations are higher and the complexity of the material is less, the analytical task is less demanding. HPLC is the preferred technique, but a simpler assay, based on optical density or fluorescence, may be feasible for some types of preparation.\textsuperscript{(67,106)}

3.3 25-Hydroxy and 1,25-Hydroxyvitamin D in Serum, Plasma and Breast Milk

Vitamin D shares with several other vitamins the property that a dietary source of the preformed vitamin is not the only biological source of the vitamin. It is, however, the only vitamin that is formed by the action of sunlight on a precursor within the skin, and it is the extent of exposure to ultraviolet (UV) light (of a limited range of wavelengths), rather than the amount of the precursor present, which is critical for the amount of de novo formation. Because of this, wide natural variations in the amount of exposure to sunlight (latitude, season and clothing) are critical in determining whether sufficient vitamin D is produced de novo, or whether food sources are essential, in order to achieve adequate status and freedom from the classical vitamin D deficiency diseases: rickets and osteomalacia. Status is measured

\textsuperscript{a} All contact details correct May 1999.
biochemically by blood analysis and there are two principal and important circulating forms of the vitamin: 25-hydroxyvitamin D and 1,25-hydroxyvitamin D. The 25-hydroxy form reflects the sum of the contributions to the vitamin from food and from the action of UV light on the skin, and this is the analyte that is normally used to define biochemical status. However, the 1,25-dihydroxy form is the active functional (hormone-like) metabolite, whose concentration indicates biological efficacy, so that measurement of this metabolite may also be necessary if there are biological or pathological reasons why the interconversion pathway(s) might be disrupted. The principles behind these metabolic processes and the practical choices for the status analyst, are discussed in greater detail in several reviews.\(^{107–111}\) Although the measurement of vitamin D per se is important for food analysis and for the study of tissues other than blood, its value as a clinical status index is limited.

There are many published methods for 25-hydroxyvitamin D based on HPLC. A selection of publications is listed.\(^{112–137}\) Somewhat simpler procedures, with a more rapid throughput rate, have been developed on the principle of specific binding proteins or specific antibodies to synthetic analogues of the naturally occurring vitamin, which generally require a radioactively labeled form of the vitamin as a marker of the extent of binding and hence of the concentration of the unlabelled analyte in the biological sample extract.\(^{118–129}\) Although the outcome of independent assessment of RIA-based commercial kit assays has not always been favorable,\(^{130}\) in the author’s laboratory this choice of assay has proved adequate for survey work requiring long-term reproducibility and procedural simplicity.\(^{129}\) There have been several studies using MS\(^{131,132}\) and some studies of hydroxylated derivatives of vitamin D other than the well-known 25-hydroxy and 1,25-dihydroxy vitamin D.\(^{115,133}\) An EQAS in the UK for serum or plasma is run by Mr Graham Carter, DEQAS, QA Working Party, Charing Cross Hospital, London W6 8RF; tel: +44 181 846 7074; fax: +44 181 846 7009; email: g.carter@cxwms.ac.uk.

For lactating mothers, the concentration of vitamin and its hydroxylated metabolites varies with the status of the mother. The measurement of breast milk concentrations\(^{39,116,134}\) can therefore provide additional status information.

### 3.4 Vitamin D and its Derivatives in Foods and Pharmaceuticals

There are two main forms of vitamin D in foods: vitamin D\(_3\) (cholecalciferol), which is derived (in vertebrates) from the action of sunlight on 7-dehydrocholesterol, and vitamin D\(_2\) (ergocalciferol), which differs only in the presence of a double bond at C-22–C-23. Vitamin D\(_3\) is derived from ergosterol, which is found in plants, fungi and invertebrates. There are smaller amounts of the 25-hydroxy derivatives of those compounds, present in some animal tissues, and there may be significant amounts of previtamin D\(_3\), which is the intermediate between 7-dehydrocholesterol and vitamin D\(_3\) and possesses about half of its antirachitic activity in experimental animals.

The older, but still potentially useful, bioassay for vitamin D activity of foods is the “rat line test”, which measures the potency of the test substance to induce new calcification in the tibia, radius or ulna of a vitamin D-deficient rat, and hence to form a deposit of silver after staining with silver nitrate (the silver nitrate is converted to silver phosphate by reaction with the deposited calcium phosphate, and then to metallic silver by photochemical reduction).

Modern assay procedures depend on HPLC after saponification (if necessary, to remove triglycerides), extraction into a nonpolar solvent, evaporation and re-solution in the mobile phase. Preliminary cleanup procedure(s), such as solid-phase extraction, are likely to be necessary before the analytical separation and quantitation. Both normal-phase and reversed-phase HPLC systems have been used; representative selections of these have been reviewed.\(^{1,5,11}\) As with the other fat-soluble vitamins, pharmaceutical preparations can be assayed by similar procedures, but simpler alternatives may be appropriate.\(^{67,106}\)

### 3.5 Vitamin K in Serum, Plasma and Breast Milk

Until quite recently, the technical difficulties associated with the measurement of vitamin K (phylloquinone and menaquinone) contents of body fluids were such that status measurements had to depend on indirect measurements, or “functional” indices, such as the efficiency of blood clotting in vitro, or the accumulation of undercarboxylated blood proteins which were specifically caused by a lack of vitamin K (e.g. PIVKA), and most recently by undercarboxylated osteocalcin.\(^{135}\) These are extremely sensitive and valuable status indices, but for some purposes, such as the comparison of dietary vitamin K intakes with blood vitamin levels, it has become necessary to develop the analysis of vitamin K per se in serum, plasma and breast milk. (The last was especially important because breast-fed babies are at relatively high risk of vitamin K deficiency, and a variety of interventions have been devised to decrease this risk, including the provision of vitamin K supplements for nursing mothers to raise their breast milk levels.)

Because of the low concentration of vitamin K in body fluids and the lack of a specific and sensitive physical property, chemical derivatization process or RIA, its quantitation required the development of highly efficient HPLC assays, usually with at least two sequential
separation stages, to achieve an adequate purity and a high enough concentration for accurate quantitation by fluorimetry or electrochemical detection. Some of these procedures have focused specifically on vitamin K (alias phylloquinone: the principal form of vitamin K that is present in plant foods); others have included the measurement of the series of menaquinones from bacterial sources that share vitamin K activity, although the relative biopotencies are not known precisely. (135–146) Phylloquinone has also been quantitated by a stable isotope-dilution gas chromatography/mass spectrometry (GC/MS) assay. (150) Tissue assays have been developed for experimental metabolic studies in humans and animals. (136,147,149,151,152) After many years in which its relevance for human nutrition was largely ignored, the importance of adequate intake and status has recently received attention, which is reflected by the greatly increased numbers of publications.

An EQAS for vitamin K assays has recently been made available in the UK: Dr Alison Cox or Dominic Harrington, Haemophilia Centre, St Thomas’ Hospital, London SE1 7EH, tel: +44 171 928 9292; fax: +44 171 401 3125.

3.6 Vitamin K in Foods and Pharmaceuticals

Assays of vitamin K in foods should include both phylloquinone and the menaquinones of bacterial origin. Since good physicochemical assays for this vitamin have only recently become available (and most food table compilations do not yet have values for vitamin K because its content in many foods is not known accurately), the availability of a bioassay has been critically important. The most commonly used procedure depends on the increase in blood clotting time that is observed in young chicks after feeding a vitamin K-deficient diet, and the fact that test substances containing vitamin K will reduce this clotting (prothrombin) time, towards the normal value.

Because vitamin K is destroyed by strong alkali, the removal of triglycerides before extraction requires enzymatic hydrolysis. Vitamin K can be extracted into nonpolar solvents or into supercritical (liquid) carbon dioxide. HPLC can be of the normal or reversed-phase type and the preferred detectors are of the fluorescent or electrochemical type, since these are both more sensitive and potentially more specific than the standard optical density type for substances like vitamin K. Examples of procedures developed between 1988 and 1998 have been described. (1,5,11)

4 WATER-SOLUBLE VITAMINS

4.1 Vitamin C in Serum, Plasma, White Cells, Urine and Breast Milk

In principle, the measurement of vitamin C concentrations and status should be easier and more straightforward than that of some other vitamins, because it is present at higher concentrations and has a characteristic reducing activity, which can be harnessed on the basis of colorimetric assays linked to redox dyes. In practice, however, the task of devising accurate and reliable vitamin C status assays has proved difficult, partly because of its rapid oxidative degradation in solution and partly because of interference by other components of body fluids, tissues, foods and so on. Since the early studies on vitamin C and scurvy which relied on animal bioassays, there have appeared dye-reduction methods, methods linked to transition-metal-ion reduction, methods linked to the formation of colored osazones with dinitrophenylhydrazine, methods linked to the formation of fluorescent adducts with orthophenylene diamine, HPLC methods with optical density, fluorescence or electrochemical detection, GC of volatile derivatives and GC/MS methods. (153,154)

With the advent of user-friendly HPLC apparatus, this approach now tends to be favored because it is reasonably specific and is less subject to interference, especially if combined with a relatively specific detector, such as the newer electrochemical or coulometric devices. (156,161,162,164,166,168,170,173,175)

Because of the problem of rapid degradation, it is essential that vitamin C be preserved efficiently in the samples that are collected, either by acidification with a chelating acid or by adding a reducing agent, which must not interfere with the assay-detection system. A variety of alternative procedures have been described. (160,167,176–179) With care, it is possible to preserve samples for more than a year at low temperatures and with suitable stabilizing agents.

In the author’s laboratory, a fluorescence-based assay in a centrifugal analyzer (180) has proved satisfactory for plasma vitamin C analysis in survey samples, and this technique compares consistently well with more time-consuming HPLC-based assays. Vitamin C assays have begun to utilize CE (181–183) and GC/MS is also proving to be a powerful alternative for certain specific tasks and for method validation. (154,184,185) The NIST QA scheme, described for vitamins A, E and carotenoids, also runs a plasma vitamin C QA scheme.

Today, vitamin C status is usually measured by serum or plasma concentrations, which vary between undetectable levels in depleted subjects, up to concentrations around 100 µM in people with a generous intake. For several decades, however, there was a preference for the use ofuffy coat (total white cell) vitamin C, which was shown, in animal models, to be a more accurate reflection of whole body status. This has now fallen into disfavor, partly because the fieldwork procedures are complex and time-consuming and partly because the result is very sensitive to variations in the proportions of the different types of white cells in theuffy coat, which in turn is affected by infections and so on. Serum or plasma
concentrations of vitamin C (and of other water-soluble vitamins) are sensitive to recent dietary intakes of rich food sources or supplements, but this potential problem can be minimized by collecting the blood sample after an overnight fast. The concentration of vitamin C in urine is less useful as a status indicator, partly because of instability (which varies with pH and other urinary constituents), and partly because it varies with variations in kidney function. Breast milk vitamin C concentrations do vary with variations in status, but they are rarely used to investigate it, partly because the range is narrower than that in plasma.

### 4.2 Vitamin C in Foods and Pharmaceuticals

There are several potential problems that can complicate the assay of vitamin C in foods. First, some foods in some countries may contain the unnatural isomer of L-ascorbic acid: D-erythorbic acid or D-isoascorbic acid, which may be added, especially to cooked meats, as a color preservative and to reduce the formation of carcinogenic nitrosamines from the nitrite (which is added as an antimicrobial agent). The D-isomer of vitamin C has very similar chemical properties to those of ascorbic acid, but it has little of its biological potency because it is poorly absorbed and is rapidly excreted. Therefore, a separation of the two isomers (generally by HPLC) is necessary if the D-isomer is present. Second, as noted earlier, ascorbic acid is easily oxidized, especially in the presence of transition metal ions; therefore its extraction into a preservative medium and subsequent analytical steps must be performed with careful attention to antioxidant precautions. Most extracts of foods contain a significant proportion of the oxidized but biologically active form of the vitamin, dehydroascorbic acid, which may be present in the native food per se, or which may be formed by oxidation during the extraction procedure. This must be included in the final assay. There are many variants of food vitamin C assays described in the literature. Rich sources of the vitamin without interfering substances can be assayed by several relatively simple physicochemical assays (e.g., the measurement of dye reduction), but less-rich sources generally require more complex assay procedures.

Bioassay procedures for vitamin C are cumbersome and time-consuming: they are generally based on the rate of maturation of the odontoblast cells in the incisor teeth of guinea pigs who have been receiving a diet which is deficient in vitamin C. It is necessary to use guinea pigs, because most other species, (other than humans and the higher primates), can synthesize vitamin C de novo from sugars and do not require a dietary source of the vitamin.

For physicochemical assays of the vitamin, extraction into a chelating acid is required and this should typically be metaphosphoric acid, or a mixture of metaphosphoric acid and acetic acids. For those extracts that can then be assayed without further separation, the choice lies between the classical reaction with 2,6-dichlorophenol indophenol, or a related dye, which is stoichiometrically decolorised by the reductive action of vitamin C, provided that all of it is present in the reduced form. A wide variety of reducing agents cause positive interference in this assay, however. Another relatively crude assay, which is only adequate for some fruit drinks or pharmaceutical preparations, is the measurement of the optical density at 267 nm (pH 6.0), before and after the copper-catalyzed oxidation of the vitamin. A more specific fluorometric assay, which has the advantage that it includes both ascorbic and dehydroascorbic acids because the former is deliberately oxidized to the latter, depends on the reaction of dehydroascorbate with o-phenylene diamine to give a fluorescent quinoxaline (see section 4.1). Several methods have been used to convert ascorbic acid to dehydroascorbic acid in this assay; the most specific is ascorbate oxidase enzyme, isolated from certain plants. A semiautomated version of this assay was adopted by the Association of Official Analytical Chemists (AOAC) for the determination of vitamin C in foods in 1990. HPLC has undoubtedly become the most reliable procedure for vitamin C analysis, especially as it is the only technique (of those that are widely available) that can distinguish between the D- and L-isomers of the vitamin. In addition, it is possible to measure dehydroascorbate by running the assay with and without a reducing agent, used to convert the dehydro form to the reduced form. Detection can be achieved by optical density, or preferably by electrochemical (or coulochemical) detection, the latter being considerably more sensitive and specific. Column types can be weak anion exchange, or ion exclusion, or reversed phase, preferably with an ion-pairing agent, usually an organic amine, with suitable precautions to avoid the precipitation of metaphosphate salts on the column. A large number of alternative procedures have been described. In addition, CE methods have been developed and GC/MS has also been described. The use of guaicol peroxidase as an alternative to ascorbate oxidase for the specific oxidation of ascorbic acid in a crude spectrophotometric assay has been described and a variety of flow injection analyses, some of which employ immobilized enzymes, have been reported. These and other simplified procedures are likely to be suitable for many types of pharmaceutical preparation with relatively high concentrations of the vitamin.

### 4.3 Thiamin (Vitamin B1) Indices in Blood, Urine and Breast Milk

For many years, the assessment of thiamin status was principally by urine analysis and was based on the
principle that thiamine could be oxidized completely to the fluorescent derivative, thiochrome, by alkaline ferricyanide treatment. This provided a reliable and sensitive measure of status in individuals and populations with relatively generous intakes of the vitamin, because the excess of intake over requirements was almost quantitatively excreted in the urine. In severely depleted or partially depleted subjects, however, the test was less discriminatory. For this and other reasons, including the difficulty of collecting an accurately timed urine sample, the enzyme reactivation test based on red cell transketolase activity was developed by Brin, described by Sauberlich et al. and Bates. This depends on the principle that with progressive tissue thiamine depletion, certain thiamin cofactor-dependent enzymes such as red cell transketolase become progressively depleted of their essential cofactor and therefore lose enzyme activity. Addition of the missing cofactor in vitro restores at least some of the lost activity. The extent of depletion and hence tissue status can be estimated in terms of the ratio of reactivated to nonreactivated enzyme activity, in vitro. The advantages of this approach are that it is highly sensitive to status variations in the critical range of moderate-to-severe depletion, and because it depends on a ratio of two enzyme activities, any procedural variations that may affect the absolute activities (pH, temperature, assay components and so on) are less important than they would be for activity measurements per se.

Although the measurement of thiamin status by the red cell transketolase activation coefficient has been widely used especially in population surveys, it does have some disadvantages, notably that the cofactor-depleted apoenzyme is slowly destroyed in vivo, that the red hemolysates needed for the assay need careful preservation before the assay and that there are no EQAS, or well-established validation procedures, for the assay. Direct thiamin assay procedures have been improved and made gradually more sophisticated since the late 1970s. Many of these have made use of recent advances in HPLC and the measurement of blood or red cell concentrations of thiamine phosphate esters has thus become an attractive alternative to the existing status assays.

The thiamin content of breast milk does not reflect maternal status to a degree that can make it useful as a status assay, and other functional assays of thiamin status have generally proved too cumbersome and not sufficiently reliable for widespread adoption.

4.4 Thiamin (Vitamin B₁) in Foods and Pharmaceuticals

Thiamin is present mainly as the cofactor, thiamin diphosphate or thiamin pyrophosphate (TPP) which is noncovalently bound to apoenzyme protein. It can be extracted without loss of vitamin activity at acid or neutral pH, but in alkalai it is easily destroyed by oxidation. Indeed, one of the most commonly used assay procedures relies on its oxidation to the inactive product, thiochrome, by alkaline ferricyanide. It can also be inactivated by UV irradiation or exposure to sulfite, which cleaves apart the two halves of the molecule. Extraction from foods is achieved either by heating with dilute (0.1 N) hydrochloric acid, typically at ca. 108 °C for plant foods such as cereals, or at 121 °C for animal foods, or by treatment with wide-spectrum proteolytic enzymes, e.g. those of fungal (diastase) and plant (papain) origin.

The soluble extracts that are obtained by these extraction procedures can be assayed either by microbiological growth assays (Lactobacillus fermentum or L. viridis-cens), or by fluorimetric assays, which may or may not require HPLC separation to achieve an initial purification of the vitamin. AOAC fluorimetric assays of thiamin in food extracts rely on open column chromatography followed by a simple extraction of the oxidation product, thiochrome, into butan-2-ol, before the measurement of its fluorescence. HPLC-based methods have been devised, which either separate thiamin and then convert it to thiochrome in a postcolumn reaction, or which oxidize the thiamin in a precolumn reaction and then separate the thiochrome before fluorimetric quantitation. Examples of these two alternative approaches are listed. GC separation has also been employed.

4.5 Riboflavin (Vitamin B₂) Indices in Blood, Urine and Breast Milk

As with thiamin, the earlier studies of riboflavin status and requirements depended on the measurement of urinary excretion, preferably in a timed urine sample. This procedure has similar limitations to those encountered for thiamin, and as a test of status it has now largely been replaced by the red cell glutathione reductase test. Like transketolase for thiamin status, glutathione reductase in red cells loses its riboflavin-derived cofactor, FAD, progressively during tissue riboflavin depletion, and the extent of this depletion is accurately reflected in the ratio of reactivated to nonreactivated enzyme activity in vitro. The activation coefficient, which is the ratio of reactivated to nonreactivated enzyme activities, increases from 1.0 (no difference) in a fully replete subject, to values well above 2.0 in severe deficiency. The normal range is usually deemed to be from 1.0 to 1.3 or 1.4, depending on the details of the assay procedure. This test has proven to be rugged and reliable; it is adequately discriminatory for population studies and it has been widely used and adopted. Nevertheless, the problems that exist for the
transketolase test are also true to some extent for the glutathione reductase test and there remains a need for concentration-type assays.

Riboflavin and its esters can be assayed by a wide range of techniques. Advances in urinary riboflavin assays have been described.\(^{215–217}\) Other developments, such as luminometric assay\(^ {218}\) and competitive-binding assay, based on specific binding proteins have also been described.\(^ {219–222}\) HPLC assays\(^ {216,223–227}\) and enzyme-based assays have been described.\(^ {228,229}\) Clearly there is now a wide range of choices and the particular selection will depend on the particular application.

Unlike thiamin, the riboflavin content of breast milk could be a moderately useful indicator of maternal status,\(^ {39}\) although it has not often been used for this purpose.

### 4.6 Riboflavin (Vitamin B\(_2\)) in Foods and Pharmaceuticals

Riboflavin is relatively stable to heat and to variations in pH, except when exposed to light, when it is rapidly and irreversibly degraded. The product of light-catalyzed degradation in alkaline solution is the highly fluorescent compound, lumiflavin or 7,8-trimethylisoalloxazine, and this forms the basis of the majority of nonbiological assay procedures for riboflavin. In foods, the vitamin occurs as free riboflavin, as riboflavin phosphate (FMN) and as the more complex enzyme cofactor FAD. There are also forms of riboflavin that are covalently bound to certain enzymes, but these are generally unavailable as food sources of the vitamin.

Like thiamin, riboflavin is usually extracted from foods by hot dilute mineral acids such as 0.1 N hydrochloric acid, typically by autoclaving at 121 °C, which converts FAD to FMN. Enzyme preparations such as fungal diastase are used, especially if complete conversion of FMN to FAD. Enzyme preparations such as tyrosine decarboxylase apoenzyme, has been used,\(^ {253}\) and offered as a commercial kit assay for the measurement of pyridoxal phosphate and hence of vitamin B\(_6\) status. The use of microbiological assays for vitamin B\(_6\) analysis, which were used for status measurements in early studies, and which remain a mainstay of food vitamin B\(_6\) analysis, are not commonly used for status measurements now, being too cumbersome and incompatible with modern clinical laboratories.

Unfortunately there is poor agreement between the different indices of vitamin B\(_6\) status, each of which is prone to a different set of confounding factors which can complicate the interpretation of vitamin B\(_6\) status. There is some ongoing research that may resolve these problems. Meanwhile it is probably advisable to use a combination of several status indices if possible. Breast milk vitamin B\(_6\) concentrations vary with variations in maternal vitamin B\(_6\) intake,\(^ {39}\) but are seldom used to determine status.

There are a number of functional indices of vitamin B\(_6\) status which focus on specific intermediates of amino acid turnover, but these are of research interest, rather than being in routine use, e.g. for surveys.

### 4.7 Vitamin B\(_6\) Indices in Blood, Urine and Breast Milk

Vitamin B\(_6\) occupies a somewhat paradoxical and atypical position, in that severe and overt deficiency is hardly ever encountered (it is not a characteristic of poor quality third world diets), yet it remains a potential problem for optimal nutrition, because evidence from several sources indicates that the ratio of this vitamin to other dietary components, particularly to protein, may be suboptimal for many human populations. A variety of assays for the vitamin itself or its degradation products (notably pyridoxic acid), and a variety of functional status assays have been proposed and developed.\(^ {16}\) Among the latter are the pyridoxal phosphate-dependent glutamate and aspartate aminotransferases that occur in red blood cells. Enzyme reactivation assays with pyridoxal phosphate in vitro have been developed which are analogous to the transketolase assay for thiamin status and the glutathione reductase assay for riboflavin status. In competition with this approach is the direct measurement of several forms of vitamin B\(_6\), or of pyridoxal phosphate, in serum, plasma or whole blood samples.\(^ {239–252}\) Although HPLC separation and fluorimetric detection have been widely used for the measurement of vitamin B\(_6\) in blood,\(^ {239–247,249,254}\) the use of a pyridoxal phosphate-requiring enzyme, stripped of its cofactor, such as tyrosine decarboxylase apoenzyme, has been used,\(^ {253}\) and offered as a commercial kit assay for the measurement of pyridoxal phosphate and hence of vitamin B\(_6\) status. The use of microbiological assays for vitamin B\(_6\) analysis, which were used for status measurements in early studies, and which remain a mainstay of food vitamin B\(_6\) analysis, are not commonly used for status measurements now, being too cumbersome and incompatible with modern clinical laboratories.

Vitamin B\(_6\) occurs in several different forms in foods. In unfortified foods the principal forms are pyridoxal,
pyridoxal phosphate, pyridoxamine phosphate and pyridoxine glucosides; fortified foods may also contain pyridoxine. Some of these forms are tightly bound to protein, and the sensitivity of vitamin B₆ to light-catalyzed degradation requires the use of rigorous precautions to exclude short-wavelength light during the analytical procedures. A major degradation product, formed from pyridoxal phosphate in vitro is the fluorescent pyridoxic acid 5'-phosphate, which is biologically inactive. The pyridoxine glucosides that occur in considerable amounts in plant tissues have a lower biological potency than the nonglucosidic forms of the vitamin, further complicating the relationship between the analytical values and the vitamin potencies of native foods.

Generally, foods are first treated with mineral acids such as dilute hydrochloric acid, under autoclave conditions, to release vitamin B₆ from the food matrices. If more detailed information is required about the forms that are present in the native foods, then an extraction at low temperatures with protein denaturants such as trichloracetic, metaphosphoric acids and so on, may be preferable. Treatment with β-glucosidase can be used to release pyridoxine from the glucosides and to measure the percentage of glucosylated vitamin present in the food. Other enzymes, such as proteases, have also been used to achieve gentle release of the vitamin from the food matrix.

Microbiological growth assays of vitamin B₆ in food extracts have used yeasts, Saccharomyces carlsbergensis (uvarum) or Kloeckera apiculata, and these have been used alone, or in combination with partial cleanup procedures, or chromatography. Fluorimetry, with or without HPLC separation has also been used and a range of procedures have been described. (1, 11, 104, 241, 242, 244, 254) Procedures for pharmaceutical preparations are also available. (67, 106)

4.9 Folate Indices in Blood, Urine and Breast Milk

The measurement of folate status, together with that of vitamin B₁₂, has for many years been a standard function of those routine hematological laboratories which include “hematric nutrient” assays in their armamentarium. Both nutrients are related to megaloblastic (macrocytic) anemia, and are therefore relevant to the diagnosis of this and related hematological abnormalities. The importance of subclinical folate deficiency, and of folate status in general, has become an important public health issue, because of the discovery that it is linked to the risk of neural tube defects (spina bifida, anencephaly) during very early pregnancy, and that it may be linked to vascular disease risk, via its effect on circulating homocysteine concentrations.

Both serum (or plasma) and red cell folate concentrations can give status information. The serum (plasma) assay is the more widely used and is simpler to perform, but it is also more affected by day-to-day fluctuations. The concentration in the red cells, which is much higher than that in plasma, is fixed at the time of production of the cells in the bone marrow and is therefore an integrated average index, representing a four-month period. However, it needs to be measured in a hemolyzed whole blood sample (the conjugate enzyme in the plasma being needed to release the monoglutamate form from the intracellular polyglutamate complex); it requires a hematocrit measurement and the sample needs to be stored with a reducing agent such as ascorbic acid. Storage conditions for the samples require careful attention. (255)

Traditionally, folate has been measured by a microbiological (growth) assay, using L. casei. The older rather cumbersome nephelometric assays using test tubes have now been modified to make use of the technology of ELISA plates and their automated readers. (256–258) With the discovery of a specific folate-binding protein in milk, alternative assays have been developed on the competitive protein-binding principle and marketed as a range of commercial kit assays, which are widely used by laboratories performing routine clinical or population survey work. (259–264) The problems of interlaboratory harmonization of these and other routine assays have not yet been fully solved (261–263) and there is a need for a “gold standard” assay, perhaps based on MS. (265, 266) However, the existence of EQAS for folate and B₁₂ in blood samples gives some degree of QC for these assays, even though the different versions of the assay do not give identical results. Contact details for these QA schemes are: (in the UK) Dr M.J. Lewis, National EQAS (UK), tel: +44 161 720 2483; fax +44 161 720 2886; (in the USA) College of American Pathologists Survey (Illinois), tel: +1 847 832 7000; fax: +1 847 446 8807.

Blood and tissue folate concentrations and, in particular, the study of the many different forms of folate that occur in tissues, require efficient separation and sensitive detection techniques, such as those of HPLC. A range of alternatives is available (267–274) and research in this field is intense. Although urine is not generally a useful source of information about intact folate, folate degradation products (275) and in particular their use for stable isotope folate labeling (turnover) studies (276, 277) are being studied in urine.

Folate in breast milk is not a useful source of information about maternal status. (39) There are several functional indices of folate status, of varying degrees of specificity and usefulness. These include plasma homocysteine (which is strongly dependent on folate status, but is also affected by other B vitamins), the excretion of formimino glutamic acid (FIGLU) after a standard histidine dose, the deoxyuridine suppression test, which measures the efficiency of the de novo
pathway of thymidine synthesis, and the nuclear lobe count of circulating polymorphonuclear leukocytes. All of these are research, as distinct from routine clinical or epidemiological, tools.

4.10 Folate in Foods and Pharmaceuticals

The assay of folate in foods poses a major challenge because of the multiplicity of forms that are present, their limited stability and the complexities posed by variable bioavailability, especially of the polyglutamate forms. The tetrahydro forms of folate present in foods are easily oxidized, and some of the oxidized forms are biologically inactive. For this reason, it is advisable to include a reducing agent, usually ascorbic acid, in the extraction medium, and to minimize exposure to high temperatures or pro-oxidant conditions. Because of the great complexity of the folate polyglutamates that occur in foods and tissues, it is common practice to simplify the structure by an enzymatic deconjugation to the monoglutamate forms during, or immediately after, the initial extraction process. Some procedures use thermal denaturation of proteins, others rely entirely on combination of enzymes, e.g. proteases to liberate protein-bound folate, \( \alpha \)-amylase to degrade starch and folate conjugates from various sources to deconjugate the folate polyglutamates.

The three main approaches to the final assay and quantification steps have been microbiological growth assays, generally with \( L. \) casei, radioassays, using a competitive protein-binding principle and HPLC. Microbiological assay has the potential advantage that, with the correct choice of conditions, it should be possible to achieve equal potency for all biologically active forms of folate in the extracts. In practice this has proved difficult and there remains a serious degree of uncertainty about the reliability of the \( L. \) casei-based assays for food folate analysis. Radioassay-based techniques also suffer from similar problems, because it is very difficult to achieve and maintain assay conditions in which all (and only) the biologically active forms of folate have equal affinity for the chosen folate binder. Although some laboratories have used this approach, it appears to have serious drawbacks.

A considerable number of HPLC-based assays have been described and there is a useful review. The use of GC/MS is finding important applications in this area. The problem of monitoring pharmaceuticals is much less difficult than that of food analysis, because the only form that is usually present is pteroylglutamic acid, which is stable and easily measured.

4.11 Vitamin B\(_{12}\) Indices in Serum, Plasma and Breast Milk

Not only are folate and vitamin B\(_{12}\) closely linked metabolically by their involvement in one-carbon transfer reactions, they are also similar with respect to the choices of status assays that are available: namely microbiological, competitive protein binding and HPLC. Because undiagnosed vitamin B\(_{12}\) deficiency due to pernicious anemia or related conditions can cause irreversible neurological damage, it is imperative that early diagnosis is made; hence the development of several commercial kit assays for clinical use, generally for use in hospital hematology laboratories. Initially, these were based on the semispecific “\( R \)-binders”, which failed to distinguish between vitamin B\(_{12}\) and some structurally related, but biologically inactive corrinoids. These were replaced by intrinsic factor-based binding assays, which possess greater specificity and have proved to be more satisfactory.

The most recent development in this field is the use of fluorescent or chemiluminescent end-points, rather than radioisotope-labeled ligands, for protein binding assays for both folate and vitamin B\(_{12}\).

More detailed investigations of vitamin B\(_{12}\) status and its metabolism have required HPLC or GC/MS techniques. Because serum vitamin B\(_{12}\) (the usual clinical status assay) may fail to detect a deficiency in some individuals and some metabolic states, additional measurements based on the circulating vitamin B\(_{12}\)-binding proteins or a functional assay based on serum or urinary concentrations of MMA have been developed. Raised levels of MMA provide a specific indicator of tissue vitamin B\(_{12}\) deficiency, which is becoming of increased usefulness now that the initial problems of accurate measurement by GC/MS or CE, have been overcome. Other functional assays for vitamin B\(_{12}\) are also shared by folate, e.g. raised plasma homocysteine, the deoxyuridine suppression test and increased polymorphonuclear leukocyte lobe counts. The Schilling test specifically tests for impaired absorption of vitamin B\(_{12}\) using radioactive cobalt-labeled vitamin B\(_{12}\) in vivo. Breast milk vitamin B\(_{12}\) levels do vary with maternal status and this is of potential concern for those nursing mothers whose dietary intake is extremely low (e.g. vegans) or those with B\(_{12}\) absorption defects.

4.12 Vitamin B\(_{12}\) in Foods and Pharmaceuticals

Vitamin B\(_{12}\) in foods is, like folate, relatively susceptible to degradation during extraction; it may be destroyed by strongly acidic or alkaline conditions and it is also susceptible to strong oxidizing or reducing agents. Extraction is designed to liberate protein-bound forms of the vitamin and to convert them to the more...
stable forms, cyanocobalamin or sulfitocobalamin. This is usually achieved by heating in buffers under mildly acid conditions: metabisulfite can be used to achieve conversion to the sulfito form.

Microbiological assay is achieved by growth assays using *L. leichmannii* (now *L. delbruecki* (lactis)), or by the protozoan *Ochromonas malhamensis* Radioassay procedures, usually based on intrinsic factor as the specific protein binder and ^*57*Co-labeled cyanocobalamin as the tracer, have been used successfully. HPLC-based methods and GC/MS-based methods are potentially available but have not yet been widely used. The form that is present in pharmaceuticals is cyanocobalamin, which is stable and fairly easily quantitated.

### 4.13 Niacin Indices in Blood, Urine and Breast Milk

Whereas the measurement of niacin status was a priority during the outbreak(s) of pellagra in the first half of this century, especially in the southern states of the USA, it has had a lower profile in recent years and the assay procedures have therefore not progressed. The most widely used status assays are those based on urinary excretion of its degradation products, and whereas the early assays were relatively crude and based on the formation of a fluorescent derivative of N^1^-methylnicotinamide alone, more recent versions have separated and quantitated both the N^4^-methyl derivative and the pyridone breakdown products, thus achieving a more reliable picture. It has been suggested that an N^1^-methyl nicotinamide: pyridone ratio less than 1.0 in urine may indicate a deficiency of niacin.

Breast milk concentrations are moderately responsive to maternal status. Studies have suggested that the concentration of niacin-derived compounds formed from niacin in blood fractions may give useful information about niacin status, and although this has not yet been developed into a routine status assay, it appears to be of significant research importance.

### 4.14 Niacin in Foods and Pharmaceuticals

Studies of the niacin potency of foods need to take account of the fact that there are two main diet-derived sources of body niacin stores: preformed niacin (nicotinamide and its coenzymes and nicotinic acid) and the precursor amino acid, tryptophan. Tryptophan contents can be measured by amino acid analysis after alkaline hydrolysis (tryptophan is destroyed by acid hydrolysis) and it is usually assumed as an approximation that one sixtieth of the dietary tryptophan is available for niacin synthesis.

Nicotinic acid and its amide are chemically stable, but some of the niacin in cereals may be locked up in the unavailable complex, trigonelline, which can only be liberated by alkali treatment (as occurs in the cooking of Mexican tortillas). Food extraction for analysis generally uses mineral acid extraction under autoclave conditions (e.g. 1 N sulfuric acid), although gentler conditions may be preferable for some foods. Final assay quantitation is either by microbiological assay using *L. plantarum* or *K. apiculata*, by colorimetry involving a reaction with cyanogen bromide and sulfanilic acid, or by HPLC with optical density detection. GLC-based methods have also been used. Niacin in pharmaceutical preparations is generally in the form of either nicotinamide or nicotinic acid, and both forms have been used in large daily doses for specific therapeutic purposes.

### 4.15 Biotin Indices in Blood, Urine and Breast Milk

Although biotin is an essential vitamin, overt biotin deficiency in humans is rare and is usually associated with inborn (genetic) errors of metabolism; therefore few analytical laboratories are called upon to measure biotin status. Biotin concentrations in plasma or urine can be measured by a microbiological assay, and this was the traditional procedure for many years. Recently, specific protein-binding assays, based on the specific biotin-binder avidin or other specific binders, have been developed. Recent studies of urinary excretion products promise to provide more specific information. As with most vitamins, HPLC has proved useful for the separation and quantitation of biotin and its catabolites. A status assay based on the in vitro reactivation of the biotin-requiring enzyme, lymphocyte propionyl CoA carboxylase, appears promising.

The concentrations of biotin in plasma and in red blood cells are similar, and there is little information to suggest whether either one or the other is preferable as a source of status information. There is little information about the variability of biotin in breast milk. Thus studies of biotin status indicators remain at an early stage of development.

### 4.16 Biotin in Foods and Pharmaceuticals

Biotin is relatively stable, but can be destroyed by extremes of pH and temperature and by powerful oxidizing agents. There are bound forms, notably biocytin, in foods and tissues and for foods of animal origin it is necessary to extract with high concentrations of strong mineral acids at high temperature (e.g. 6 N H_2SO_4 in an autoclave). Different tissues require different extraction conditions for maximum yield. Proteinolysis, for example with papain, may be effective and preferable.

Microbiological growth assay of extracts is achieved using *L. plantarum* or by radioassay using the specific
4.17 Pantothenate Assays (Status, Foods, Pharmaceuticals)

Pantothenate deficiency is practically unknown in humans and is only likely to arise if pantothenate antagonists are ingested. Older studies of the pantothenic acid content of blood and tissues were based on microbiological assays, but enzymatic, mass spectrometric and other approaches have now been reported. There is little information about its variation in breast milk. Measurements of the pantothenic acid contents of foods are needed, particularly in the context of the development of food tables, and both microbiological and chemical (e.g. specific binding) procedures have been developed for this purpose.

4.18 Other Substances with Vitamin-like Properties

There are, of course, innumerable substances present in foods that may have beneficial and protective properties, even though specific deficiency syndromes for them have not been described except in special circumstances, such as inborn errors, or particular diseases, or at extremes of the age range. The analysis of dietary and blood carotenoids has already been referred to, in sections 3.1 and 3.2; some carotenoids are vitamin A precursors and most are antioxidants, although their relevance to human health remains poorly understood. Another, numerous group of dietary antioxidants is the polyphenols, including the bioflavonoids. HPLC-based assays are being developed to quantitate these, both in foods and in body fluids such as blood and urine. Several of the essential and quasi-essential components of our diet are lipidic: these include the essential fatty acids, plus the major phospholipid components choline and inositol and the important lipid-carrier L-carnitine. These can be assayed by the classical techniques of lipid analysis (GLC and so on) or by enzyme-based methods. Other quasi-essential dietary components, such as taurine, are amino acids and can be assayed by the classical procedures of amino acid analysis.

During most of the twentieth century, analytical technology has been unable to measure large numbers of diverse chemical substances in a single run, but it is likely that this limitation will diminish in the future, with the perfection of new and powerful recognition procedures, such as controlled fragmentation MS, combined with more efficient preliminary separation methods. It should, therefore, become possible to quantitate a much greater range of nutrients than has been possible hitherto and to start to investigate the long-term effects of subtle dietary modulation, focusing on lesser-known components, which may have been ignored in the past. These may prove even more significant for long-term health than the 13 substances which have already, largely for historical reasons, been given the status of vitamins.

5 PROBLEMS ENCOUNTERED IN INTERPRETING VITAMIN STATUS INDICES

For most vitamins, the amount present in the deeper tissues of the body and the amount obtained from the diet over a period of time bear some relationship to the concentrations that are found in serum or plasma, blood cells, ratio of urinary excretion and so on, so that one or more of these indicators can be used as status and/or intake indicators for each of the vitamins. However, there are many confounding factors that can disturb and complicate the relationship between the status indices and the intakes or body stores of the vitamins which they aim to reflect. First, the amounts in serum or plasma may be modulated by specific binding proteins: this is particularly true for vitamin A (retinol) in plasma, but to a lesser extent also for several other vitamins. Both vitamins E and K are concentrated in circulating lipoproteins or lipids and their serum or plasma levels are thus proportional to the lipid levels as well as to body stores. Another important factor that can affect serum or plasma concentrations of most nutrients is the acute phase reaction: some nutrients are transferred into the plasma by infections or inflammatory processes, others are transferred out, so that the ratio of circulating levels to body stores changes for the duration of the acute phase reaction. This is especially true for retinol, but it is also observed for several water-soluble vitamins. Some vitamin concentrations are also sensitive to variations in kidney function, which can alter the overall composition of the circulating fluids.

Vitamin concentrations within the cellular components of the blood should be less seriously affected by the disturbances listed above, and indeed it is true that cellular concentrations can be better long-term status indicators for some of the vitamins, such as folate, thiamin and riboflavin. However, there are no red cell status indicators available for the fat-soluble vitamins or for vitamin B12. Although red cell indicators can be useful, they may
also be complicated, e.g. by anemia, or by certain genetic
diseases. White cell-based indices should also be valuable,
but the complexity and variability over time of the white
cell fraction and the relative difficulty of isolating pure
cell types, has made this approach difficult to develop.

Urinary concentrations of B-vitamins were favored as
indicators in the early years of vitamin studies, but they
have proven less attractive lately, because of the difficulty
of collecting accurate 24-h (or other timed) urine samples,
and because the rate of urinary excretion is not very
sensitive to status variations, when status is relatively
poor. This arises from the fact that the vitamins are
normally only excreted into the urine when the amount
in the blood rises above that of tissue requirements.
Degradation products may be formed at a rate that is
proportional both to intake and to status, and this has
been used for studies on niacin and vitamin B₆.

6 SUMMARY

The vitamins are a diverse group of compounds, both
chemically and analytically, because they comprise a
range of biomolecules whose common properties reside
solely in the fact that they are essential dietary compo-
nents, which are needed in relatively small amounts to
sustain life and good health. In addition, the major analyt-
ical challenges that they present are derived from the facts
that (1) there is a need to quantitate them in a wide range
of biological matrices, which include both foods and body
fluids (for status indices); (2) the concentrations that are
present are usually very low and the ratio to other com-
ponents, which can be chemically very similar, is small;
(3) they may be present in several or many chemically
diverse but biologically interconvertible, forms; (4) some
of them are labile to heat, extremes of pH, degradative
enzymes and so on and (5) there is no single analytical
approach that can quantitate all of them together within
a biological matrix.

Vitamins have been divided broadly into fat- and
water-soluble groups and each of these has been further subdivided, mainly on a functional basis. Historically,
the B-group vitamins were measured by various micro-
biological assays and others were measured (if at all) by
semispecific colorimetric assays. Nowadays, there are sev-
eral more powerful techniques available, which include
high-pressure liquid chromatography, with a range of
detectors operating over a continuous range of selective
modalities; RIA and ELISA-based techniques, which use
specific protein-binding selectivities, enzyme reactivation
techniques for certain B-vitamin status assays, and so on.
The use of MS is gaining ground and can be combined
with several other separation techniques, such as GLC,
CE and so on. Measurement of vitamins in simple phar-
maceutical mixtures (vitamin supplements etc.) is now
reasonably straightforward.

The technical advances that these methodologies
represent have greatly broadened the horizons of the
vitamin analyst, and have permitted even some of the
more difficult biological matrices to be addressed. However, the unsolved challenges of accurate vitamin
analysis show little sign of receding, and there are very
few, if any, laboratories worldwide that are currently
able to measure all of the known vitamins in all known
biological matrices. This remains a major challenge and a
goal for the twenty-first century.

Polymers and Rubbers: Introduction

T. Provder
Olmsted Falls, USA

1 BACKGROUND

The technological directions of polymer-related industries at the beginning of the 21st century have been determined by the operative business and societal driving forces of the last decade of the 20th century. The resultant technological directions affect the product development cycle and shape characterization needs of the materials required. The role of polymer characterization, analysis and testing in the product development cycle is depicted in Figure 1. Product development is no longer a direct straight-line process from product design to product performance, bridged by polymer and product characterization, analysis and testing. The product development cycle is subject to the many constraints produced by the operative temporal business and societal driving forces. These constraints have grown during the last decade and include the following:

- product development costs
- raw material supply
- shorter product development and market introduction cycles
- energy conservation
- waste reduction
- governmental regulations
- safety, health, and environmental considerations
- product quality and consistency
- emphasis on customer needs and satisfaction
- public consumerism
- improved product–process–customer economics
- global competition
- improvement of shareholder value

As can be seen from Figure 1, the role of polymer characterization, analysis and testing is to facilitate product development in a highly constrained environment. For example, polymer product development has been strongly influenced by environmental considerations and government regulations. The “Clean Air Act” of 1990 is the driving force behind the development of coatings with significantly lower volatile organic content. Plastic packaging is being developed with built-in environmental degradability. For plastic containers, it has become very desirable to use plastics that can be readily recycled. The Environmental Protection Agency in the United States is increasingly taking a “cradle to grave” philosophy with regard to the minimization of organic volatiles generation, minimization of product waste generation and energy usage associated with the chemistries used in the development of a commercial product.

The global operative business and societal driving forces of the last decade have caused polymer-related industries to focus strongly on their core businesses and technological competencies. This focusing has produced a more targeted approach to product development and a significant change in corporate Research and Development culture. The product development process and its associated commercialization is no longer a sequential process from Research and Development to product introduction into the marketplace. The process has become highly nonlinear, nonsequential, and iterative, with many concurrent parallel paths. Often, product Research and Development, process scale-up, plant manufacturing, and quality assurance overlap, occur in parallel and feed back to each other in order to speed up product innovation and shorten the product development and market introduction cycle.

On a more fundamental level, very few new commodity building blocks (monomers) are expected to be developed because of economic, environmental and regulatory considerations. Increased strategic use of low levels of specialty building blocks, coupled with innovations in polymer reaction processes, is expected in order to add value to a polymer product within acceptable economic constraints. In general, structure–morphology–property considerations are becoming of paramount importance in the development of new products. Examples include high-performance engineering plastics and composites that require strategically designed polymers, polymer alloys, and blends; and strategically designed polymers for electronic and biopolymer applications. It is not a question of what building blocks are put together, but how to put them together to make unique polymer products. This approach requires polymer structure–morphology control down to the molecular level in order to enhance and improve properties in a cost-effective manner. A recent example of this approach is the development of new polyethylene materials with unique end-use properties through the application of

metallocene chemistry in conjunction with innovative reaction processes.

The polymer product development process depicted in Figure 2 shows that polymer characterization methodology is required in each step of the process to achieve two goals:

1. characterize the molecular architecture and physical properties produced by a particular polymerization method, mechanism and process;
2. characterize the polymer product resulting from product processing in order to relate surface and bulk properties and morphologies to application and end-use properties.

This process also is highly iterative, with changes sometimes being required in the polymer design or product processing, or both, during the product development and market introduction cycle.

Due to the ever-increasing complex nature of polymeric products, measurement of average properties is no longer adequate to characterize and elucidate the nature of such complex materials. A combination of polymer characterization and analysis methods, the use of “hyphenated” characterization techniques and/or multidimensional analytical approaches is required to provide a synergism of analytical and characterization information to establish structure, property and morphology relationships that can form a knowledge bridge between polymerization mechanism and end-use performance.

On the basis of an ever-expanding list of constraints to product development produced by the operative global business and societal driving forces, polymer characterization analysis and testing can be expected to take on an even greater role in the polymer product development cycle during the 21st century. This chapter on the application of polymer characterization and analysis methods to polymers and rubbers is a reflection of that expectation.

2 ABOUT THIS SECTION

This section is organized into four main areas of instrumental applications to polymers and rubbers: chromatography; spectroscopy; morphology; and thermal analysis/rheology. Each of these four instrumental application areas include the key polymer characterization methodologies and techniques that are expected to be highly relevant for analyzing complex polymer systems now and in the future. Each of these four main areas is by no means all-inclusive. However, reference will be made to other sections and articles in this encyclopedia that complement, overlap, reinforce and fill any voids or omissions in the four instrumental applications areas cited above.

2.1 Chromatography

There are seven articles in the chromatography part of this section, which include the following topics: (1) Gas Chromatography in Analysis of Polymers and Rubbers, (2) Inverse Gas Chromatography in Analysis of Polymers, (3) Supercritical Fluid Chromatography of Polymers, (4) Size-exclusion Chromatography of Polymers, (5) Coupled Liquid Chromatographic Techniques in Molecular Characterization, (6) Field Flow Fractionation in Analysis of Polymers and Rubbers, and (7) Temperature Rising Elution Fractionation and Crystallization Analysis Fractionation. This is a rather comprehensive section on the application of chromatography methods to the analysis of polymers and rubbers.
POLYMERS AND RUBBERS: INTRODUCTION

Continued in these articles are many examples of the use of hyphenated techniques, manifested by the use of multiple detectors with a given chromatographic method, as well as the use of multidimensional chromatographic methods. The reader also is referred to the Coatings section on Gas Chromatography in Coatings Analysis for very closely allied polymer applications. In addition, the reader is referred to some of the theory and instrumentation sections and articles. In particular, the articles in the Mass Spectrometry section on Gas Chromatography/Mass Spectrometry and Liquid Chromatography/Mass Spectrometry are worth noting, as well as many of the articles in the Liquid Chromatography section, with particular emphasis on the articles on Gradient Elution Chromatography and Supercritical Fluid Chromatography. For the reader interested in the process applications of chromatographic methods and their potential applications to polymer reactors, the reader is referred to the section on Process Instrumental Methods and the articles on Chromatography in Process Analysis.

2.2 Spectroscopy

The spectroscopy part of this section consists of six articles on infrared spectroscopy and two articles on nuclear magnetic resonance spectroscopy. The infrared spectroscopy articles cover the following applications: (1) Infrared Spectroscopy in Analysis of Polymers and Rubbers, (2) Infrared Spectroscopy in Analysis of Polymer Structure–Property Relationships, (3) Infrared Spectroscopy in Analysis of Polymer Crystallinity, (4) Infrared Spectroscopy in Analysis of Polymer Degradation, (5) Infrared Spectroscopy in Analysis of Plastics Recycling, and (6) Near-infrared Spectroscopy of Polymers and Rubbers. The infrared spectroscopy articles cover a wide range of applications and do include examples of infrared spectroscopy-hyphenated techniques. Although this section does not contain an article on applications of Raman spectroscopy, the reader is referred to the Coatings section for an article called Infrared and Raman Spectroscopy and Imaging in Coatings Analysis and to Ultraviolet and Visible Molecular Absorption and Fluorescence Data Analysis in the section on Electronic Absorption and Luminescence. The reader also is referred to the theory and instrument section on infrared spectroscopy for details on instrumentation, infrared theory, data analysis and interpretation.

The articles on nuclear magnetic resonance in the section on Polymers and Rubbers cover the following applications: (1) Nuclear Magnetic Resonance, Solid State in Analysis of Polymers and Rubbers, and (2) Nuclear Magnetic Resonance, Imaging of Polymers. For applications involving the liquid state and polymers and coatings, the reader should see the article on Nuclear Magnetic Resonance of Coating and Adhesive Systems in the Coatings section. Also, the reader is referred to the theory and instrumentation section on nuclear magnetic resonance and electron spin resonance spectroscopy for details on instrumentation, nuclear magnetic resonance theory, data analysis and interpretation. The article on high-performance liquid chromatography with nuclear magnetic resonance in this section is of particular relevance for polymer-related applications.

Although there are no articles on mass spectrometry and fluorescence spectroscopy in the Polymers and Rubbers section, the reader is referred to the articles in the section on Mass Spectrometry and the section on Electronic Absorption and Luminescence with emphasis on the articles Fluorescence Lifetime Measurements, Applications of, and Fluorescence Imaging Microscopy. The reader also is referred to the article on Atomic Spectroscopy in Coatings Analysis in the Coatings section, for its obvious relevance to other polymer systems. For the reader interested in process applications involving spectroscopy, with potential applications to polymer reactors, the reader is referred to the section on Process Instrumental Methods, with specific attention to articles on Near-infrared Spectroscopy in Process Analysis, Ultraviolet/Visible Spectroscopy in Process Analyses, Nuclear Magnetic Resonance and Magnetic Resonance Imaging for Process Analysis, and Raman Spectroscopy in Process Analysis.

2.3 Morphology

The morphology part of this section consists of five chapters covering a range of applications with articles as follows: (1) Atomic Force Microscopy in Analysis of Polymers, (2) Neutron Scattering in Analysis of Polymers and Rubbers, (3) X-ray Scattering in Analysis of Polymers, (4) Positron Annihilation Spectroscopy of Polymers and Rubbers, and (5) Pyrolysis Techniques in the Analysis of Polymers and Rubbers. The reader is referred to the Coatings section for the articles on Microscopy of Coatings to evaluate how these techniques are used to assess the morphology of polymeric based coatings systems. Additionally, the theory and instrumentation section on X-ray photoelectron spectroscopy and Auger electron spectroscopy should be perused. The reader should also access the application section on surfaces, which has several articles on a range of microscopy techniques which have relevance for polymer surface morphology characterization. One area of morphology analysis not included in this section is the determination of the particle size of polymeric particles. There is an entire application section devoted to particle size analysis. The vast majority of
these articles are highly relevant to the measurement and characterization of polymeric particles.

2.4 Thermal Analysis/Rheology
The thermal analysis/rheology part of this section consists of five articles covering a range of applications that are highly complementary to one another in terms of information that can be generated on polymeric systems. These articles are as follows: (1) Thermogravimetry of Polymers, (2) Dynamic Mechanical Analysis of Polymers and Rubbers, (3) Mechanical Properties of Polymers and Rubbers, (4) Dielectric Spectroscopy in Analysis of Polymers, and (5) Surface Energetics of Polymers and Rubbers, Characterization of. The Coatings section is once again recommended to the reader for its polymer-related articles on Mechanical Properties of Solid Coatings, Thermal Analysis of Coatings and Rheology in Coatings, Principles and Methods. The reader is additionally referred to the theory and instrumentation section on thermal analysis for details on instrumentation, thermal analysis methods theory, data analysis and interpretation.

It is hoped that the articles in this section on applications of polymer characterization analysis and testing will provide the reader with an information and knowledge base relevant to the technical challenges of 21st century product analysis, problem solving and product development.
Atomic force microscopy (AFM), in which a sharp probe is employed for profiling surfaces with unique resolution, has developed into an invaluable multidisciplinary technique for advanced characterization of polymer materials. In its basic function, AFM provides high-resolution imaging of surface structures between the scales of a few nanometers to hundreds of micrometers. This capability is useful for quantitative analysis of surface microroughness of technological surfaces with high sensitivity and accuracy. The direct visualization of polymer structures, from single macromolecules to granular and lamellar nanostructures, to microphase separation and other morphological patterns, makes AFM an important complementary tool for many of the techniques (light scattering, chromatography, optical and electron microscopy, X-ray diffraction analysis, etc.) employed in polymer analysis.

The advances in AFM of polymers are related to a better understanding of tip–sample force interactions and their use for examination of local sample properties. Different responses of the probing tip to surface locations with different mechanical and adhesive properties are the key for compositional imaging of heterogeneous polymer systems. Compositional mapping with AFM, which does not require any special sample treatment, substantially enhances its microscopic value. Visualization of individual components in block copolymers, polymer blends and semicrystalline materials can be performed with nanometer resolution. In addition to lateral compositional imaging, AFM probing of subsurface structures can be achieved for polymer samples with rubber-like top layers.

A further expansion of AFM applications is expected with the imaging of polymers at different temperatures. Monitoring of polymer structural changes at thermal phase transitions could help in the understanding of polymer melting, crystallization, recrystallization, glass transition and physical aging. In such applications, AFM will complement various thermal techniques.

The review describes the basics of AFM, practical aspects of its applications to polymers and presents a broad range of examples illustrating the main trends in AFM of polymer materials.

1 INTRODUCTION

Polymer macromolecules and polymer materials are characterized by a number of analytical methods that help us learn about their chemical structure, chain organization and mobility, polymer morphology and nanostucture, mechanical and thermal behavior and many
other properties. For example, diffraction and microscopy techniques are widely used for examination of structural hierarchy in polymer samples. Electron microscopy is a direct imaging tool that presents structures in real space. Diffraction techniques (X-ray, neutron, light, electron, etc.) are reciprocal space methods and a conversion of their data into a real space demands the use of structural models which might be subjective. Analysis of polymer thermal transitions and mechanical properties of polymers at different temperatures is performed using a number of calorimetric and mechanical methods. These methods and some others (NMR (nuclear magnetic resonance), vibrational spectroscopy, dielectric spectroscopy, optical birefringence and dichroism) indirectly provide valuable information about structural organization in polymer materials. Most of the methods mentioned are well established and routinely applied in research and industrial laboratories. Advantages of these analytical techniques as well as their shortcomings are known, and the latter limit our knowledge about the structure–property relationship in polymer materials.

The increasing importance of these materials in modern technology demands a more detailed characterization of polymers. Progress in polymer synthesis allows precise control of polymer chain structure and, therefore also allows fine tuning of architecture and properties of novel macromolecular structures and polymer materials. Studies of new catalysts, chain structure and its branching, and monitoring the self-assembly of polymer molecules into building blocks of supramolecular architecture, are only a few of the tasks to be accomplished. Also, the rapid development of nanotechnology and the important role of polymer materials in this field requires better understanding of polymer behavior and properties on micrometer and submicrometer scales. This knowledge is invaluable for the engineering of polymer nanomaterials, which will be top players in a variety of technological applications.

Many expectations for advanced polymer analysis are related to the use of AFM. This method was introduced in 1986 for high-resolution imaging of surfaces and was first applied to polymer samples in 1988. The original idea was to reach atomic scale resolution in the profiling of surface structures and it was successfully demonstrated on a number of different materials. With the development of AFM applications, it appeared that it is a multidisciplinary technique with applications far beyond those of traditional microscopy. The sharp tip used in AFM, which has an apex tens of nanometers in diameter, can serve not only as a profilometry stylus but also as a tester for probing mechanical, adhesive and even more specific (magnetic, electric, optical, thermal, etc.) sample properties. One of the first important lessons learned from the AFM studies of polymer and biological samples was the need for low tip–sample forces to prevent damage to these soft materials. Since the introduction of an AFM tapping mode, which is most suitable for studies of soft materials, progress in its applications to polymer materials became substantial. Nowadays, this field is of interest to an increasing number of researchers in academic and industrial laboratories.

In this chapter, AFM applications to polymer materials will be overviewed. This goal is challenging because of the rapid developments in this field. Therefore, the main idea is to collect examples with longevity. A short introduction describes the history of scanning probe microscopy (SPM), the family of methods in which AFM is the most important player. Different AFM modes are illustrated by images of polymer samples. AFM applications to polymers will be described by numerous examples, which present direct visualization of polymer chains, nanometer-scale architecture of crystalline polymers, block copolymers, three-dimensional (3D) compositional maps of heterogeneous polymer systems, and polymer morphology together with its changes at thermal phase transitions. From the presented results, the reader will get an idea how AFM complements a large number of other analytical techniques and why for some polymer samples it can provide data which are not accessible by other means. Future expectations in AFM of polymers will be summarized at the end of the article.

2 SCANNING PROBE MICROSCOPY AND ITS DEVELOPMENT

2.1 Basic Principles of Scanning Probe Microscopy

The invention of scanning tunneling microscopy (STM) in 1982, which allows a real-space visualization of surface structures with atomic resolution, has revolutionized microscopy. By placing a sharp metallic probe in the immediate vicinity of a conducting or semiconducting sample and applying an electric potential between these two electrodes, it is possible to detect a tunneling current and to use it for atomic-scale imaging, Figure 1(a). The latter has been achieved using a piezoceramic actuator, which pivots the probe over equicurrent profiles with subangstrom precision.

A most remarkable example of the first STM applications is the image, which reveals a surface Si (7 × 7) reconstruction pattern, Figure 1(b). This image unambiguously demonstrated that atoms and atomic-scale defects could be visualized with the new technique and the observed packing motif confirmed one of the structural models of reconstruction on the Si surface. Initially, STM measurements were conducted in UHV (ultrahigh vacuum) but similar studies could also be performed under ambient conditions. Such possibilities have

attracted a large number of researchers to this field, especially after the first commercial scanning tunneling microscopes became available in 1988. It has been established that STM images actually present maps of partial electron density (electron density at the Fermi level) measured at the tip–sample separation. Therefore, the rational interpretation of STM images demands a theoretical analysis, and a direct correlation between the image and surface topographic structure might be misleading. Another difficulty of STM is related to the possibility of strong tip–sample force interactions, which are often not taken into account. Because the tip force could induce surface deformation, on some samples the STM images have been actually obtained on the deformed surfaces. Despite these difficulties, STM is used for surface studies of conducting and semiconducting materials in a large number of research laboratories worldwide. STM studies of conducting polymers and carbon materials (carbon fibers, carbon black, etc.) have been performed to visualize surface topography, morphology and molecular-scale order.

The invention of AFM was initiated by a natural desire to extend STM applications by making possible atomic-scale imaging of nonconducting materials. Instead of tunneling current, a more universal tip–sample force interaction was employed for surface imaging in AFM. A simple optical lever method was successfully used for detection of small forces between the apex of a microfabricated tip, which is positioned at one end of a tiny cantilever, and a sample surface. Figure 2(a–c). In this method, the bending of the cantilever due to small tip–sample attractive and repulsive forces is magnified on a positional photodetector and a related signal is used for profiling the sample surface at a constant force level. Because the tip–sample force is proportional to the total electron density of the top surface atoms, AFM images more directly relate to surface topography than STM images. In contrast to STM applications, the first AFM studies were conducted under ambient conditions, and only later the possibility of AFM measurements in UHV was demonstrated. Imaging samples under liquid and in electrochemical environments are also possible with both techniques.

With developments in AFM applications the validity of this technique became evident. High-resolution profiling of surfaces has facilitated observations of atomic-scale surface steps, atomic and molecular lattices in a large number of inorganic and organic crystals. Observations of single DNA molecules by AFM have promoted its application to different biological samples. It is also understood that the tip–sample force interactions in AFM should be considered while imaging soft materials (polymer and biological materials). Normal and lateral forces between the tip and the sample in contact AFM mode are of tens and hundreds of nanonewtons. Minimization of these forces is needed for nondestructive imaging of soft samples. This has been achieved in imaging under liquid. With the introduction of a tapping mode, in which lateral forces are practically eliminated, AFM studies of soft materials have further broadened.

The success of STM and AFM applications led to the development of a number of related SPM techniques, which are used for mapping surface magnetic, electric, thermal, and optical properties. These methods are also known as magnetic force microscopy (MFM),
Figure 2 (a) AFM set-up showing optical lever detection employed in AFM for detection of the cantilever deflection caused by tip–sample force interactions. (b) Scanning electron micrograph of etched Si probe, which consists of a 125-µm long cantilever and a sharp tip. (c) Apex of a Si tip.

electric force microscopy (EFM), scanning capacitance microscopy (SCM), scanning near-field optical microscopy (SNOM), and scanning thermal microscopy (SThM), and so on. A large number of applications have been developed with these techniques, however, a separation of the effects of these interactions and surface topography is a key problem in such applications. In MFM and EFM this problem is solved using a two-pass lift technique. In this technique, the topography is measured in the first scan and magnetic or electric properties (using appropriate probes) are measured in the second scan over the same area. In the second scan,
probe motion reproduces the measured surface profile (feedback is off) but with a vertical lift of 20–50 nm. Changes in frequency or phase of the oscillating ferromagnetic probe during the second scan reveal magnetic surface structures or surface variations in dielectric constant when a conducting probe is used. In this way, the effect of long distance electromagnetic forces is separated from those of mechanical tip–sample forces. The height and frequency images in Figure 3(a) and (b) give a practical example of how surface topography and magnetic pattern of video magnetic tape are visualized in MFM. The magnetic structures of the film are seen in the frequency image. This was an example showing that the measurement of the surface topography is a practical requirement of all scanning probe methods.

There is no doubt that AFM is the leading scanning probe technique. It allows examination of practically any kind of sample and is applied in increasing numbers of industries, while other SPM techniques are rarely used for industrial applications. So far, the semiconductor and data storage industries have benefited most of all. Automated AFM systems have been introduced for on-line control of roughness of Si wafers\(^{11}\) and of pole tip recession in magnetic heads.\(^{12}\) The characterization of polymer materials with AFM, which substantially complements more traditional microscopic and diffraction methods, is developing rapidly in research and development laboratories in the plastics, rubber, paint, biomaterials and paper industries.

### 2.2 Atomic Force Microscopy Instrumentation

A generic scheme of the atomic force microscope is shown in Figure 4. In this configuration, a piezoceramic scanner carries the probe over the sample. In the alternative configuration, Figure 2(a), the scanner moves the sample whereas the probe is fixed. Scanners include two cylinders, one assigned for vertical \(z\) motion. Because of nonlinearity, creep and other features inherent in polycrystalline piezoceramic materials, a linearization of the 3D motion of the scanner is performed with software correction. Different lateral and vertical standards are used for scanner calibration. After that, measurements of lateral dimensions can be performed with angstrom resolution and measurements of vertical dimensions can even attain subangstrom resolution. The maximal area, which is commonly covered by piezoceramic scanners, is \(\sim\)150 \(\mu\)m on the side. Surface corrugations up to 5 \(\mu\)m in height can be profiled. Additional \(X\)-\(Y\) stages are employed for positioning surface regions of interest under the probe.

Another key feature of AFM, which defines its unique capabilities for surface imaging, is the high sensitivity of the optical lever detection. Surface imaging is realized with the electronic feedback system, which utilizes a signal from the four-segment optical positional detector. (Vertical segments are used for measurement of the cantilever deflections caused by normal tip–sample force. Horizontal segments are used for measurement of the cantilever torsion that is due to lateral tip–sample forces.) This signal, often called the error signal, is the difference between the actual value of the normal tip–sample force and its set-point value chosen by the operator. The differential signal is used to adjust the vertical probe–sample separation and keep the tip–sample force interaction constant during scanning. All these functions are realized using an electronic controller, which also communicates with an image acquisition computer. The variations in the cantilever–sample separation are converted into a height image with bright (dark) contrast assigned to high (low) surface locations.

Commercial scanning probe microscopes are manufactured by a number of companies in the USA, Japan, the United Kingdom and Russia. The most popular microscopes are the Nanoscope IIIa™, MultiMode™ and the Dimension™, which are shown in Figure 5. Both instruments can be equipped with tensile stages and heating accessories. The MultiMode™ is a compact microscope, which provides a whole spectrum of AFM modes and requires only minimal vibration and acoustic isolation. The limited size of the sample (\(\leq 2\) cm in diameter) is a limitation, which is overcome by the Dimension™ microscope. A close-up of the Dimension™ AFM head and a large sample (8 inch, or 20 cm, wafer) is shown in Figure 5(b). However, with the increase in instrument size more protection from acoustic and vibrational noise is necessary. This is accomplished by placing the microscope into a special enclosure, Figure 5(c). With the further use of AFM instruments in the semiconductor industry, the size of microscopes used

is increasing making possible examination of 300-mm wafers and their automatic on-line handling by robotic systems.

2.2.1 Atomic Force Microscopy Probes

Microscopic probes are invaluable components of all SPM instruments, and their quality substantially defines the practical value of these techniques. There are a large variety of AFM probes (the integrated cantilever and tip) that are commercially manufactured. Most of them are microfabricated from \( \text{Si}_3\text{N}_4 \) or Si. Various coatings are applied to these probes in order (1) to increase a reflectivity of their backside for improved detection of the bouncing laser beam, (2) to provide electric or ferromagnetic properties of the probe, (3) to implement a thermosensitive element at the apex, (4) to improve the tip apex wear. The cantilevers have triangular or rectangular shapes and their length varies in the 100–400-nm range. The tips are pyramidal or conical and several micrometers in height. The opening angle of these tips varies in a range between 30–90° and the apex radius can be as small as 5 nm. Specially prepared tips are required for profiling deep trenches (hundreds of nanometers wide and up to several micrometers deep). Triangular-shaped \( \text{Si}_3\text{N}_4 \) probes are most often applied to contact mode measurements and their spring constants are in the 0.1–0.01-N m\(^{-1}\) range. There are a larger variety of etched Si probes. Their rectangular-shaped cantilevers have stiffness in the broad range from 0.1 to 500 N m\(^{-1}\) and their resonant frequencies are in the range from 10 to 500 kHz. Soft probes are applied to contact mode measurements, whereas stiff probes are required for the tapping mode in order to retract the tip from a sample surface in each oscillation cycle. (Adhesion and capillary forces caused by liquid contamination layers attract the tip to the surface.) However, stiff probes might cause a surface deformation of polymer samples even in the tapping mode. Therefore,
an optimal choice of the probe is needed for imaging of a particular polymer sample. The quality factor (\(Q\)) of the probe cantilever is another parameter to be considered in tapping mode applications. High-\(Q\) cantilevers are more sensitive to small force variations, whereas low-\(Q\) cantilevers are more suitable for precise height measurements in the tapping mode and also for fast scanning.

Besides the probes described, which are routinely used in AFM studies of polymers, several types of modified tip are known. For example, chemically modified probes can be prepared by coating the Si tips with gold and by chemisorption of thiolo-organics on gold surfaces. In these ways, tips with different chemical functionality and different physical and chemical properties can be prepared. Applying such probes one might expect detection of specific force interactions between the modified probes and surface locations with a different chemical nature. There are a number of results, which indicate such effects. However, it is difficult to assign these results exclusively to the different chemical natures of these surface regions without considering differences in their mechanical and adhesive properties. The latter makes the interpretation of these effects much more complicated. Another problem of chemically modified Si or Si\(_3\)N\(_4\) probes is the integrity of the coating at the apex during scanning that cannot be checked directly.

### 2.2.2 Sample Preparation

The attractive features of AFM applications to polymers and other materials include the ability to perform measurements under ambient conditions or under liquid with minimal sample preparation. Many polymer samples (thin layers, films, fibers) can be examined without any preparation. Spin-cast films and those prepared by dipping the substrate into polymer solutions are proper samples for AFM. In studies of the morphology and nanostructure of crystalline polymers, the flat sample surfaces can be prepared by melting a piece of polymer on flat substrate (mica graphite, Si wafer) and cooling. Afterwards a crystallized sample can be separated from the substrate, and the flat polymer surface which was in contact with the substrate, is most suitable for AFM studies. For polymer materials, which are prepared by extrusion, compression or injection molding, flat sample surfaces for AFM study can be made by ultramicrotome.

In contrast to TEM (transmission electron microscopy), which requires preparation of ultrathin sections, polymer blocks with a flat surface are proper samples for AFM imaging. However, preparation of extremely smooth polymer surfaces is a not trivial procedure and it requires an optimal choice of knife material, and optimal temperature of the knife and the sample. AFM images reveal the imperfections of this sample preparation (scratches, chattering patterns, contamination traces, etc.) Freeze fracture of some polymer samples also can result in flat surface areas.

Another important advantage of AFM studies compared with electron microscopy is that there is no need for sample staining or coating with a metal layer. Differences in mechanical and adhesive properties of components in heterogeneous polymer systems, such as semicrystalline polymers, block copolymers, polymer blends and composites are employed for compositional AFM imaging. Compositional mapping of polymer blends and composites is successfully performed on flat polymer surfaces prepared using an ultramicrotome. However, caution should be exercised in observations of submicrometer structures and, particularly, features in the tens of nanometers size range because these features can be at least partially due to material fracture that occurs during cutting. This area has not been explored yet.

### 2.2.3 Imaging Artifacts

AFM, as well as other microscopic methods, is not free of various artifacts. Imperfections could be caused by the inexperience of the operator and related to choice of nonoptimal imaging parameters, including set-point values, scanning rate, and gains. Samples with varying roughness require adjustment of these parameters and tracking of the surface steps might be difficult. The ability to measure surface profiles while scanning in different directions (from \(-X\) to \(+X\) or from \(+X\) to \(-X\)) helps to clarify these effects and to avoid them by optimizing scanning parameters. Also specific features of piezoceramic scanners such as creep, nonlinearity, and cross effects between different axes should be taken into consideration. These effects are enhanced when the sample is tilted with respect to the microscope plane.

Most obvious artifacts are clearly seen in the images. Among these are double tip effects, when additional ghost patterns appear together with the real ones. A bad tip causes these artifacts. This might happen because of a manufacturing defect, traces of sample material which have stuck to the tip, or because of tip damage. The tip apex can be damaged and flattened while scanning hard samples. A sharp Si probe becomes dull after scanning on a Si wafer at elevated tip forces. Then imaging of surface features, which are sharper than the dull probe, leads to the appearance of the tip profiles in the images. This is inverse imaging: the sample images the tip. Periodical linear patterns with a repeat distance of 1.5–2.5 \(\mu\)m, which are often seen in the images of flat samples such as mica are caused by optical interference, which occurs on the surfaces of the sample and the cantilever. Adjustment of
the position of the detecting laser beam on the cantilever minimizes this effect.

### 2.3 Atomic Force Microscopy Operational Modes

Several operation modes have been developed in AFM. The main imaging modes, contact mode and oscillatory or tapping mode differ in the way the tip interacts with the sample, Figure 6(a) and (b). In the contact mode, the tip scans a sample surface while being in permanent contact with that surface, Figure 6(a). The cantilever deflection is a measure of the force which is exercised by the sample. The tip–sample force is maintained constant during scanning by an electronic feedback. The correct choice of set-point force is an important decision to be made by the microscopist. If a polymer sample is heterogeneous with components which have different mechanical properties, then with an increase in tip-force the height image reflects a larger tip-induced surface deformation of the weaker component. This is demonstrated in the height images, which were obtained in the contact mode at different tip forces on the sample of multilayer polyethylene (PE), Figure 7(a–c). In this sample, layers of PE with different number of branches and different densities (0.92 g cm$^{-3}$, high-density material; 0.86 g cm$^{-3}$, ultralow-density) alternate with each other. Narrow strips of high-density polyethylene (HDPE) are elevated in height images recorded at high forces. This is a result of a strong tip-induced deformation of weak layers of ultralow-density polyethylene (ULDPE). In varying the tip force, one should check if such deformation is elastic or it might cause sample damage. Therefore, in applying contact AFM mode to soft materials, one should be aware of how accurately the height image presents a surface topography.

In the tapping mode (Figure 6b), the tip comes into contact with the sample in every cycle of its oscillatory motion at (or near) the resonant frequency of the...
Atomic Force Microscopy in Analysis of Polymers

A drop in the cantilever amplitude when the sample is brought close to the probe is used to measure tip–sample forces. During scanning in the tapping mode, the probe comes only into intermittent contact with the sample surface. As a result, more soft samples can be examined in the tapping mode than in the contact mode. This is demonstrated by the height image (Figure 7d), which was obtained on a multilayer PE sample with the same probe that was used for contact mode images in Figure 7(a–c). In Figure 7(d), the area previously scanned and damaged in the contact mode is seen. Variations in the tip–sample force interactions in the tapping mode did not lead to damage of this sample. The advantages and disadvantages of both modes will be described below.

Probing the mechanical or adhesive sample properties with the AFM tip can be performed locally, at one surface point, without scanning. Force curves are recorded for this purpose. Force curves describe the probe deflection (contact mode) or variations in the cantilever amplitude (tapping mode) versus the vertical travel of the sample or the probe base towards and away from each other. Depending on the level of the tip force the surface deformation can be elastic or plastic. In the latter case, the tip makes an indent on the sample. Special probes with diamond tips, which have an apex of several tens of nanometers, are employed for such studies. After indenting, the surrounding area is scanned and the indent dimensions are determined from the AFM image obtained. Such a procedure is the basis of a nanoindentation technique that is widely used for measurements of local mechanical properties of different materials and coatings. Examples of local mechanical measurements of polymers will be discussed in section 3.3.

2.3.1 Contact Mode

In this mode, lateral scanning of the probe over the sample surface is initiated when the vertical bending of the cantilever, which is due to the repulsive tip–sample force, reaches the set-point level chosen by the operator. After this happens, lateral motion of the probe is initiated by the feedback control. Continuous motion of the probe from the \(-X\) to \(+X\) direction (fast direction) proceeds with small advances in the \(Y\) direction. Scanning rates are typically in the 0–3-Hz range and can be higher when scanning is performed on atomically flat surfaces or in submicrometer scan areas. Imaging is performed continuously and is monitored on a computer screen. Single images (typically 512 \(\times\) 512 data arrays) are collected as data files. Various filtering and data analysis procedures can be applied to AFM images. A height image of banded spherulites of poly(vinylidene fluoride) (PVDF) is shown in Figure 8(a) which reflects the surface topography of the sample. Some details of topography are better seen in the deflection (or error signal) image, Figure 8(b), which resembles a map of derivatives of topography scan lines. For many practical applications, it is also useful to record the variations of the lateral tip–sample forces. To emphasize friction effects, imaging should be performed with the slow scanning direction perpendicular to the cantilever length. Lateral force images, which are collected simultaneously with the height images, reveal surface regions that have different mechanical and adhesive properties. This is demonstrated by the images of a rubber sample, shown in figure.
Figure 9(a) and (b). Areas of different contrast, which are seen in the lateral force image, correspond to different components of this blend. Such differences might not be distinguishable in the height image.

The contact mode has proven itself capable of imaging atomic- and molecular-scale periodical lattices. Such images have been obtained for a large number of organic and inorganic crystals and also for polymers. Molecular-scale images of polymers were obtained on oriented samples of PE, polytetrafluoroethylene (PTFE), polypropylene and polybutene-I. The periodical patterns can be obtained in the height, deflection and lateral force images. The latter might provide a better contrast of the atomic-scale features. One such image is shown in Figure 10(a), where a periodical pattern of oriented PTFE is seen. Filtering of the image using a fast Fourier transform (FFT) procedure, Figure 10(b), gives a much clearer view of the chain arrangement. The interchain distance (0.56 nm) and the pitch (0.82 nm) along the polymer chains are consistent with X-ray data, which reveals a slightly twisted conformation of PTFE chains. Another AFM image in Figure 10(c) shows oriented chains of PE, which were revealed on the surface of highly oriented sample.

Several AFM studies aimed to check molecular packing in polymer single crystals and in samples prepared by epitaxial crystallization. Images of normal and cyclic alkanes, which are short chain analogs of PE, reveal molecular-scale packing of their crystals in full agreement with the crystallographic data. Crystallization of long chain molecules proceeds via chain folding and single crystals of a number of polymers prepared from dilute solutions are actually thin lamellae with a well-defined crystallographic shape. An essential question, which has not yet been answered is, how perfect is the molecular arrangement of the lamellar surface? Different structural defects, such as chain ends, loops, and “switchboard” chain segments, could cause deterioration in the perfect adjacent-reentry arrangement expected for perfect crystals. A number of atomic-scale images, which show periodical lattices of single crystals of polymers (PE, poly(ethylene oxide)) are most likely to have been obtained with the probe penetrating through the topmost surface layer (or depressing it) and thus revealing chain packing inside these crystals. Similar data have been obtained with X-ray diffraction techniques. Imaging of polymer crystal surfaces at low tip–sample forces shows a grain nanostructure of lamellar surface, which will be discussed in section 5.1.

It is worthwhile to consider critically the capabilities of atomic-scale images in contact AFM mode. When applied to thin and ultrathin layers (thickness above and below 100 nm, respectively), small and imperfect crystals, atomic-scale AFM images give structural information that might be difficult and even impossible to obtain by diffraction techniques. However, there is a definite limitation to such studies that is related to the fact that such imaging is not true atomic-scale imaging. It is most likely that several apex atoms stay in contact with the surface when the tip moves and the tip–force variations reflect the corresponding surface lattice. Therefore, in contact AFM mode observation of atomic-scale defects (e.g. vacancies) is not achieved. Later, the atomic-force defects were observed in UHV studies of several semiconductors (including Si (7 × 7) surface) when...
the oscillatory AFM mode was applied in so-called noncontact regime. An UHV environment, which is essential for detection of ultrasmall tip–sample forces, is a serious obstacle to the broadening of such applications.

2.3.2 Force Curves

Following the first applications of contact AFM mode to polymers and, particularly, to biological objects it has become evident that tip–sample forces lead to surface modification and sample damage. Therefore, one should consider the tip–sample forces in more detail using force curves. The force curve describes the cantilever deflection as a function of the scanner travel, Figure 11(a). (In practice, force curve measurements are performed at frequencies in the 1–100-Hz range.) Upon approach of the sample, a probe initially experiences a small attractive force, which causes the cantilever to bend.
downwards. Then the tip comes into contact with the sample and the cantilever deflects upward, reflecting repulsive tip–sample forces. When the sample is retracted from the probe, the tip is stuck to the sample by the capillary force. A layer of liquid contamination that presents on samples in air causes this capillary force. Therefore, a pull-off force is needed for tip disengagement and this causes hysteresis in the force curves. In some cases, the pull-off force might be used as a measure of adhesion between the probe and the surface.

The contributions of different forces acting on the probe and the samples are shown schematically in Figure 11(b). From this picture it is clear that under ambient conditions the tip force includes the capillary force of the liquid contamination layer. By adjusting the set-point deflection to the attractive force level near pull-off point, the imaging can be achieved with the lowest force possible for a given probe. However, this condition is unstable owing to possible tip disengagement and is not realized practically. Under these conditions, the capillary effect limits the minimal force for imaging in contact mode to ~5 nN. By placing the probe and the sample under liquid the capillary force could be avoided. This is seen from the comparison of force curves in Figure 12(a). In general, the tip forces under liquid can be one to two orders of magnitude less than in air. This finding had encouraged AFM applications to biological systems because measurements in the aqueous environment, which is more suitable for such samples, can be performed. However, imaging under liquid has its own limitations especially when knowledge of the material structure and

![Diagram](image)

**Figure 11** (a) When the sample approaches the tip (→, right-to-left) attractive force (point 1) slightly bends the probe down (Δ, cantilever deflection). Further sample travel will induce upward bending of the cantilever caused by repulsive forces (point 2). On reverse travel (←), the tip is stuck to the sample until the probe spring stiffness overcomes the adhesion/capillary forces (point 3). (b) Scheme of different forces acting on a probe.

![Diagram](image)

**Figure 12** (a) Force curves recorded in the contact mode in air and in liquid. (b) Force curve obtained on grafted poly(dimethylsiloxane). (Reproduced with permission from Aime and Gauthier. [23]) (c) Force curves obtained on glass and ULDPE samples. Strong deformation of the ULDPE sample (z₁ – z₂) at a cantilever deflection Δ₁ is evident from these curves.
behavior under ambient conditions is required and when interaction with liquid is not desirable.

It has been found that surface material or even a single macromolecule, when stuck to the tip, is stretched during the disengagement. In such cases, the jumps in the force curve can be associated with a break in the stretched material or bonds in single macromolecules. This situation is described in Figure 12(b) which shows the force curve, which was measured on polydimethylsiloxane surface grafted to silica substrate. First, a pull-out force is recorded when the tip becomes unstick from the surface. On further withdrawal of the probe, the cantilever bends again because the polymer material stuck to the tip is stretched and this stretching force exceeds the cantilever’s stiffness. The next disconnection happens when the “bridge” between the tip and the surface is broken. The events described happen in the tens of piconewtons force range. These highly sensitive force measurements allow mechanical properties of single macromolecules, including DNA to be evaluated, opening up another interesting research area.

Analysis of force curves in the repulsive regions shows how mechanical properties of polymer samples can be examined. When the sample is rigid, such as a piece of Si wafer or glass, the cantilever bends upwards in a linear fashion defined by the cantilever’s stiffness. For many polymer samples, their stiffness is close to that of the cantilever and the force curve could reflect the tip-induced surface deformation or a partial tip penetration into the sample. The slope of the force curve and the difference in the way the scanner travels to reach the same cantilever deflection define the tip-induced deformation of a soft sample, Figure 12(c). A more detailed analysis of the force curves in needed to clarify the effects of the sample viscoelasticity.

The important conclusion from force curve studies is that they can be applied to local probing of mechanical and adhesive surface properties. An extension of this approach is realized in another mode known as force volume. In this mode, force curves are collected at a large number of points (64 x 64, 128 x 128 or 256 x 256) in the area of interest, and the data at any particular force level is presented as a map. In this way, surface maps of mechanical properties (taken as force data at strong repulsive force levels) or adhesive properties (taken as force data in the disengagement region) can be obtained. A similar idea was implemented in the pulsed force mode, in which maps of mechanical and adhesive properties are collected at a broad range of frequencies. Mapping of the mechanical surface properties had also been achieved in force modulation (FM) mode. In FM, the probe, which scans the sample in the contact mode, is driven into a vertical oscillation with an additional piezo-actuator at its resonant frequency (5–8 kHz). This actuator is positioned at the fixed cantilever end. With the tip staying in contact with the sample, the cantilever with its base being the whole assembly periodically moves up and down (Figure 13a) and the cantilever amplitude in the deflection direction is measured by the laser signal reflected from the back of the cantilever. In other words, the force on the sample is modulated around the set-point level, which is chosen to scan in the contact mode. FM data (fast changing, amplitude in deflection) are collected simultaneously with topographic information (slow changing, averaged deflection). The amplitude response depends on the mechanical properties of the sample: on stiff surfaces the tip bounces from the sample and the amplitude is large, whereas on soft samples the tip deforms the sample or penetrates into it and the deflection amplitude is small. This is demonstrated by the images of the multilayer PE sample, Figure 13(b) and (c). The height image shows the sample topography with elevated and narrow strips of high-density PE layers. In the amplitude image, the darker contrast (larger amplitudes are coded by a darker contrast) of these narrow layers confirms their high modulus in comparison with that of the wide layers of ULDPE. Initially FM was introduced to differentiate between the responses of surface regions or components (e.g. carbon fibers in epoxy matrix) with a different elastic modulus, however, its capabilities are much broader though not well explored.

To extend the application of FM to viscoelastic materials, it was suggested that the phase shift between two periodical signals be measured, one for the driver and the other for the photodetector. In this approach, some analogy can be found between this approach and dynamic mechanical analysis (DMA), in which the phase lag between an oscillating load and the induced sample deformation are used for evaluation of the viscoelastic properties of polymer samples. Indeed, there is some correlation between the driving amplitude in FM and sample deformation in DMA, and also between the cantilever deflection in FM and the load applied to the sample in DMA. However, in AFM of polymers the sharp tip deforms a sample or penetrates into it. A theoretical description of the tip deformation of the viscoelastic media is rather complicated, and nonlinear tip–sample force interactions substantially limit transferability of AFM data to the macroscopic mechanical behavior of polymers determined in DMA experiments. An additional challenge is an appropriate description of the cantilever mechanics in FM. Also it is worthwhile to note that the combination of the contact and oscillatory modes employed in this mode restricts its applications to soft materials.

2.3.3 Tapping Mode

The need for small tip–sample force interactions has been recognized since the introduction of AFM. An
initial suggestion was to make use of noncontact imaging in a pure attractive force mode. Sensitive probes and oscillatory cantilever motion were needed for the detection of long range weak van der Waals interactions. Although several applications of noncontact AFM imaging have been developed (true atomic scale imaging in UHV, profiling of semiconductor structures with maximum resolution of few nm, etc.) progress in AFM of polymers is entirely determined by use of the tapping mode. In this mode, the tip intermittently contacts the sample for a short time thus avoiding development of the inelastic sample deformations. In the tapping mode, lateral tip–sample forces are practically eliminated, allowing this mode to be applied to a broad range of soft materials. It appears that optimization of the tip–sample forces is the main issue for most AFM applications to polymers. In one respect, minimization of the tip force is required for a gentle profiling of polymer samples. Low-force imaging, which means a small tip–sample contact area, will also be beneficial for high-resolution imaging of samples such as polymers that are not well ordered. In another respect, tapping at elevated forces is extremely useful for the compositional imaging of heterogeneous polymer systems. Therefore, it is important to demonstrate how to optimize the tip–sample force interactions in the tapping mode.

In the tapping mode, reduction of the cantilever amplitude, which is determined at (or near) the resonant frequency of the cantilever, owing to tip–sample forces is used to obtain feedback during scanning. The amplitude of the free-oscillating cantilever, $A_0$, is typically in the 1–200-nm range. Whether to use a set-point amplitude $A_{sp}$ or a set-point ratio, $r_{sp} (= A_{sp}/A_0)$ is the choice of the operator. In contrast to the contact mode, in which the cantilever deflection is directly related to the tip force, the amplitude changes do not fully determine the tip–sample forces in this oscillatory mode. For imaging the surfaces of homogeneous materials, this does not cause problems, although they might occur in imaging of heterogeneous samples with surface corrugations of a few nanometers, see section 3.1.

The driving frequency in the tapping mode is typically chosen at the resonant frequency of the probe. For systematic AFM studies at different $A_0$ and $A_{sp}$ it is important to find the resonant frequency of the probe in the immediate vicinity of the surface. Far away from the surface, the resonant frequency of the cantilever will be higher because of reduced damping of the cantilever motion in a near-surface confined environment. A typical amplitude resonance curve of the AFM cantilever resembles that of a harmonic oscillator, Figure 14(a). The frequency dependence of the cantilever phase is also shown. The phase as well as the resonant frequency of the oscillator is a sensitive measure of the forces acting on the probe. Attractive forces acting on the AFM probe cause a negative shift of its resonant frequency; repulsive forces cause a positive shift. If the phase of the oscillation is measured at the initial resonance frequency, $w_0$ (as happens in tapping mode), the phase of the oscillation will be negative (with respect to its level at $w_0$) in the attractive force regime and positive in the repulsive force regime. The phase changes are instructive for clarification of the tip–sample force interactions in the tapping mode.

The driving frequency versus distance and phase versus distance curves (Figure 14b) show how amplitude and phase of the oscillating cantilever change when the separation between the sample and the cantilever’s base is reduced. When an amplitude drop is small, a negative phase indicates that the overall tip–sample interactions are attractive. With a further amplitude drop, repulsive interactions become dominant as seen by the switch in phase from negative to positive. These interactions also depend on the magnitude...
Figure 14 (a) Amplitude versus frequency and phase versus frequency relationships for harmonic oscillator with resonant frequency $w_0$. Attractive forces cause a low-frequency shift of these curves (---), repulsive forces cause a high-frequency shift (-----). (b) Amplitude versus travel and phase versus travel curves recorded in tapping mode on high-density PE. (c) Amplitude versus travel curves obtained on ULDPE and a Si wafer.

of the initial amplitude $A_0$. When $A_0$ is small (1–5 nm), phase changes are negative at all amplitudes. Under these conditions, tip–sample interactions are always attractive. At large amplitudes (above 60 nm), the phase changes are always positive owing to the dominant repulsive force interactions. These results are typically obtained on surfaces of PE samples.

Amplitude curves recorded on polymer samples deviate from the straight line which describes the amplitude drop when the sample is hard such as Si wafer. In the latter case, the amplitude drops linearly with the sample travel and vanishes totally when the sample surface coincides with the cantilever baseline, see also Figure 6(b). (On further vertical travel the cantilever bends up and this leads to the appearance of a deflection signal similar to that in the contact mode.) On the soft samples, owing to this tip-induced deformation or even penetration, the amplitude curve is very different from that on the hard sample. As an example, the amplitude curve which was obtained on ULDPE is shown in Figure 14(c). At each $A_{sp}$ value, the difference between this curve and a straight line, which simulates the curve on the rigid sample, defines an amount of tip-induced sample deformation or of tip penetration. Several examples of imaging at different tip penetrations will be given in sections 5.1 and 5.2.

Although the force interactions in the tapping mode are described by the amplitude and phase curves, it is important to understand how $A_0$ and $A_{sp}$ influence the AFM images of polymer samples. This question was discussed earlier, and it was found that with an increase of $A_0$ and a decrease of $A_{sp}$, tip forces become stronger. An evaluation of the tip–sample forces in the tapping mode is not straightforward because the force changes in each cycle. Therefore, it will be instructive to judge these interactions by considering force-induced sample changes. The model system, a binary blend of HDPE and ULDPE prepared in a melt, can be used as a convenient model sample for examining tip–force effects. The elastic moduli of the components are quite different, therefore it becomes possible to observe tip–force-induced height changes. Height and phase images of the different sample imaging conditions are collected in Figure 15(a). The topography of the sample shows a number of bumps, which appear to be high-density PE regions. With the increase in $A_0$ and decrease in $A_{sp}$, these structures become more pronounced related to the strong deformation in their surroundings, which is ULDPE. The contrast in the phase images reveals different components of this blend, however, an assignment of “dark” or “bright” regions to individual components is rather ambiguous.

To understand better the relationship between the phase image contrast and surface regions with different densities it is instructive to analyze cross-section height and phase profiles taken along the same surface regions, Figure 15(b). These data were obtained at $A_0 = 100$ nm.
changes also become evident with high-density spots exhibiting more positive phase changes. The maximum phase difference of the stiff and soft regions is observed at \( r_{sp} = 0.4 - 0.5 \), and it gradually disappears at small \( r_{sp} \). Under the same conditions, the effective height of the “bumps” continues to increase.

The height changes in the low-density and high-density regions versus \( r_{sp} \), which were recorded at different \( A_0 \) and \( A_{sp} \), are summarized in Figure 16(a). The height versus \( r_{sp} \) curves show that at small \( A_0 \) the decrease of \( r_{sp} \) from 1 to 0.4 does not lead to any substantial height changes, and only at lower \( r_{sp} \) does the tip-induced surface deformation cause an increase of the height of the high-density regions. With an increase of \( A_0 \), the height versus \( r_{sp} \) dependence becomes different. At high \( r_{sp} \), the height has already increased and it exhibits a local maximum at \( r_{sp} = 0.5 \). With a further decrease in \( r_{sp} \), the height slightly decreases, and at small \( r_{sp} \) it increases again. The similarity in the height changes for all amplitudes at very small \( r_{sp} \) \((0.2 - 0.1)\) is most likely to be due to a loss of the “tapping” character of the probe. Under these conditions the tip spends most of the time in contact with the sample (quasicontact) and the tip-induced surface deformation is determined mostly by the cantilever spring constant and it does not depend on \( A_0 \).

The phase changes which were measured on the regions of different density at \( A_0 = 100 \text{ nm} \) and \( A_0 = 20 \text{ nm} \) are shown in Figure 16(b) and (c). In imaging with large \( A_0 \), the positive difference between the phases in the high-density and low-density regions is observed for almost all \( r_{sp} \). The maximal phase contrast between components is at \( r_{sp} = 0.4 - 0.5 \), i.e. under the same conditions as when the difference in the mechanical properties is visualized in the height images. This correlation allows the suggestion to be made that with hard tapping, the phase contrast is governed mainly by the different mechanical properties of the sample regions or components. More complicated phase behavior with contrast reversal is seen for imaging at smaller amplitudes when a more complex interplay between capillary effects, adhesive interactions and mechanical properties defines the phase changes. Therefore, imaging with larger \( A_0 \) and \( r_{sp} \sim 0.4 \) (“hard tapping”) is of more practical importance because it facilitates the assignment of phase contrast to the components with different mechanical properties. In the case of different PE, acrylic blends and elastomeric systems, stiffer components can be identified by their more positive (brighter) phase contrast in the phase images obtained by hard tapping. The great sensitivity of the phase changes to the sample heterogeneity is a key feature of the tapping mode in its application to polymers. In many heterogeneous polymer samples the differences in the elastic moduli of the components are not so drastic as in the case of the PE blends discussed above.

![Figure 15](image) (a) Height and phase images of the HDPE/ULDPE blend, prepared in a melt. The images were obtained on surface area 3 \( \mu \text{m} \times 3 \mu \text{m} \). The images at the top were obtained at \( A_0 = 20 \text{ nm} \) and \( r_{sp} = 0.7 \); the images in the middle were obtained at \( A_0 = 100 \text{ nm} \), \( r_{sp} = 0.5 \), and the images at the bottom were obtained at \( A_0 = 80 \text{ nm} \) and \( r_{sp} = 0.15 \). (b) Set of height and phase cross-sections along the 3-\( \mu \text{m} \) long regions of the HDPE/ULDPE blend. Measurements were performed at \( A_0 = 100 \text{ nm} \) and different \( r_{sp} \).

and \( r_{sp} \) in the 0.95–0.1 range. When \( r_{sp} \) is close to 1, the profile in the height image presents a true surface topography. Note that the phase curve is located almost at the zero level indicating an absence of noticeable tip–sample force interactions. This imaging regime is known as light tapping. With the decrease in \( r_{sp} \), the “bumps” become higher owing to stronger tip deformation of the soft regions. This deformation can be described as elastic because the height and phase changes at \( r_{sp} \) in the 1–0.1 range are reversible. The phase
Figure 16 (a) “Height” difference between regions of HDPE and ULDPE obtained at different $A_0$ and different $r_{sp}$. Unlinked empty diamonds correspond to $A_0 = 5$ nm; cross-hatched diamonds to $A_0 = 20$ nm; linked empty diamonds to $A_0 = 40$ nm; black diamonds to $A_0 = 80$ nm. (b) and (c) Phase differences between the regions of HDPE (open points) and ULDPE (filled points) obtained at different $r_{sp} = A_{sp}/A_0$. $A_0 = 20$ nm (c) and $A_0 = 100$ nm (b).

Therefore, even with hard tapping, the height variations in these materials are hardly distinguishable, whereas the phase contrast provides component recognition.

Phase imaging has become a useful addition to the tapping mode because the phase contrast allows visualization of different components of heterogeneous polymers. However, assignment of phase contrast is not straightforward and a number of theoretical approaches are applied to address this problem. From the experimental data, phase contrast can be assigned to variations in mechanical or adhesive properties of components or surface regions. In a more general case, phase changes in the tapping mode strongly depend on energy dissipation.\(^{(31)}\) Correlation between the energy dissipation at the tip–sample junction and the sample position is shown in Figure 17(a–c) together with the amplitude and the phase curves. All these dependencies were obtained on the surface of Si wafer.

In the absence of dissipation, when the amplitude of the oscillating cantilever is not restricted by the set-point value, the relation between the phase and amplitude of the cantilever is defined by symmetric branches $\phi = \pm \arcsin (A/A_0)$. These branches are relevant to the operation either in the attractive force regime (negative phase) or in the repulsive force regime (positive phase). In such cases (for example in the lift scan in MFM or EFM), phase and amplitude are strictly bound. Because the amplitude is kept constant (feedback is off) in the tapping mode, this relationship breaks down and phase changes are caused by the energy dissipation in the tip–sample junction, Figure 17(a–c). The experimental phase curves lie within the “arcsin” branches and the transition from the attractive to repulsive force regions means a “jump” from the lower to the upper branch, Figure 17(d). Although this transition is not specific in terms of energy dissipation, it can complicate the interpretation of phase contrast, which is defined with respect to the 90-degree level. (For simplicity this level so far has been defined as 0°). Figure 17(d) also demonstrates the correspondence between experimental data and the calculations, which were performed considering the interacting cantilever as a weak nonlinear system.\(^{(32)}\) A number of phase curves derived from the calculations, which accommodate elastic deformation, adhesion and dissipation terms ($K, w$ and $\alpha_s$, respectively), all fall within the “arcsin” branches. It was also indicated that at low $r_{sp}$ the tapping mode probe becomes a strong nonlinear vibration system. Therefore despite the fact that tapping mode results obtained on some elastomeric systems can be treated in terms of a simple harmonic oscillator\(^{(33)}\) this approach is not general. To summarize, progress in the theoretical description of the tapping mode has brought a better understanding of the probe behavior and emphasized the energy dissipation in the tip–sample junction as a primary event. However, separation of the contributions of the different interactions to the phase behavior remains a challenging problem in AFM analysis of multicomponent polymer samples.
Figure 17 (a) Amplitude, (b) phase and (c) dissipation of the cantilever as a function of sample travel. (Reproduced from Cleveland et al.\textsuperscript{31})

\[ P_{\text{tip}} = \frac{kA^2w_0}{2Q} \frac{A_0}{A} \sin(\phi) - 1 \]

where \( P_{\text{tip}} \) is power dissipated at the tip-sample junction. \( A \) is the set-point amplitude, \( A_0 \) is the amplitude of a free-oscillating cantilever and \( Q \) is the quality factor. (d) Phase versus \( A_{\text{sp}} \) under different interaction conditions. (Reproduced from Wang.\textsuperscript{32}) \( F_+ \) and \( F_- \) correspond to repulsive dominated and attractive dominated branches, respectively. Mechanical and adhesive interactions \((K = 2 \text{ GPa and } w = 0.4 \text{ N m}^{-1})\) are the same for all curves except \( F_+ \) and \( F_- \).

3 EXAMINATION OF SURFACE TOPOGRAPHY AND LOCAL PROPERTIES

A number of practical examples, which illustrate the unique capabilities of AFM in studies of polymers, are presented in sections 3–5. Many examples show how AFM complements other characterization techniques. Most results were obtained in the tapping mode, recording height and phase images. Height images reveal surface topography and characteristic morphologic features of crystalline polymers, of oriented samples and of microphase separation. In studies of homogeneous samples, phase contrast often helps to visualize fine features of polymer morphology and nanostructure. Phase imaging is invaluable for compositional mapping of heterogeneous polymer systems. In tapping mode imaging, the driving frequency is chosen at the resonant frequency of the cantilever in the immediate vicinity of the sample surface. This does not exclude the possibility that other frequencies can also be used for imaging. For recording height images, which most correctly present true surface topography, small \( A_0 \) and high \( A_{\text{sp}} \) are applied. Such conditions are most favorable for high-resolution imaging owing to the minimal tip-sample contact area. Imaging at an \( A_{\text{sp}} \) of 0.5–0.4 \( A_0 \) and large \( A_0 \) (hard tapping) was used for compositional mapping of heterogeneous polymer samples. These conditions should be considered only as a preliminary idea of those needed for imaging of polymer samples. In practice, one should use a whole spectrum of parameters to optimize AFM imaging towards the problem being studied.

3.1 Surface Topography and Roughness

Initially, high-resolution surface profilometry was a primary goal of AFM, and this feature is useful in imaging research and industrial polymer samples. Surface corrugations from several nanometers to several microns can be examined quantitatively. Two examples of surface roughness measurements with AFM are presented in Figure 18(a) and (b). Surface corrugations in the height image of poly(methyl methacrylate) (PMMA) photoresist, which was deposited on a Si wafer by spin coating, (Figure 18a) are described by the following roughness parameters: \( R_{\text{rms}}(R_q) = 0.394 \text{ nm and } R_q = 0.314 \text{ nm.} \) After chemical mechanical polishing bare
Si wafers are characterized by smaller roughness with $R_{\text{ms}}$ ($R_q$) and $R_a$ below 0.2 nm. AFM evaluation of the surface roughness of Si wafers is employed for quality control in the semiconductor industry.\(^{11}\) Considerable roughness is desirable for polycrystalline Si surfaces, which are used in the manufacture of stack capacitors, and the AFM image of the polycrystalline surface in Figure 18(b) reveals its surface roughness with $R_{\text{ms}}(R_q) = 8.113$ nm; $R_a = 6.553$ nm.\(^{34}\) Imaging with light tapping facilitates accurate roughness measurements because it provides not only a small contact area but also prevents wear of the probe apex.

The technological surfaces described above are relatively flat, and they do not require special probes, in contrast to those applied to more complicated measurements of surface structures with critical dimensions, such as steps and trenches. In order to measure angles of steep surface steps or roughness at the bottom of narrow trenches (a few microns in depth and hundreds of nanometers in width) AFM probes with special geometry are needed.

The surfaces of most polymer samples are relatively flat and can be examined with conventional Si probes. Measurements of surface roughness with AFM are useful for studies of paint and polymer coatings. The height image of acrylic paint (Figure 19a) shows a surface with averaged corrugations $R_{\text{ms}}(R_q) = 36.771$ nm and $R_a = 28.057$ nm. Graphs, which show a linear correlation of AFM data with gloss measurements at two different angles of incidence, are presented in Figure 19(b).

**Figure 18** AFM height images of a photoresist (PMMA) layer on Si wafer (a) and polycrystalline Si sample (b). Image size is $2 \mu m \times 2 \mu m$ in (a) and $3 \mu m \times 3 \mu m$ in (b).

Si wafers are characterized by smaller roughness with $R_{\text{ms}}$ ($R_q$) and $R_a$ below 0.2 nm. AFM evaluation of the surface roughness of Si wafers is employed for quality control in the semiconductor industry.\(^{11}\) Considerable roughness is desirable for polycrystalline Si surfaces, which are used in the manufacture of stack capacitors, and the AFM image of the polycrystalline surface in Figure 18(b) reveals its surface roughness with $R_{\text{ms}}(R_q) = 8.113$ nm; $R_a = 6.553$ nm.\(^{34}\) Imaging with light tapping facilitates accurate roughness measurements because it provides not only a small contact area but also prevents wear of the probe apex.

The technological surfaces described above are relatively flat, and they do not require special probes, in contrast to those applied to more complicated measurements of surface structures with critical dimensions, such as steps and trenches. In order to measure angles of steep surface steps or roughness at the bottom of narrow trenches (a few microns in depth and hundreds of nanometers in width) AFM probes with special geometry are needed.

The surfaces of most polymer samples are relatively flat and can be examined with conventional Si probes. Measurements of surface roughness with AFM are useful for studies of paint and polymer coatings. The height image of acrylic paint (Figure 19a) shows a surface with averaged corrugations $R_{\text{ms}}(R_q) = 36.771$ nm and $R_a = 28.057$ nm. Graphs, which show a linear correlation of AFM data with gloss measurements at two different angles of incidence, are presented in Figure 19(b).

**Figure 19** (a) Height image of one of 18 PVC paints. Contrast is in the 0–500-nm range. Image size is $100 \mu m \times 100 \mu m$. Statistics for the image and the box, which confines a part of the surface area (black lines) are shown beside the image. (b) The relationship between surface roughness ($R_a$) and gloss, measured at 60 (filled dots) and 20 (open dots) degrees, for 13 different paints.
Quantitative estimates of the surface roughness of various coatings provided by AFM are useful for correlation with their optical properties and appearance. AFM evaluation of surface roughness is important for samples of thin and transparent coatings on substrates which are difficult to examine by optical means.

More extensive AFM studies were performed on model systems of the paints such as acrylic latexes.\textsuperscript{35,36} AFM images reveal the morphology of latex surfaces and their packing motifs (Figure 20a). At higher magnification, the submicron structure of individual latex particles can be examined. Height and phase images of the polystyrene (PS) latex layer show only small surface corrugations on individual particles, which are noticeable only in the phase image, Figure 20(b). A "berry-like" particle structure of PMMA latex is seen in the AFM images in Figure 20(c). Again, these structural features are more pronounced in the phase image.

It is worth noting that because of the perfect shape of latex particles, which can be prepared in different sizes, they are suitable for testing the quality of AFM probes. The surface area difference (a difference between surface area of corrugated features and surface area of the flat plane), which is calculated from height images of a single latex layer, would be greater if the tip correctly tracks surface locations between neighboring particles. In this way probes that are most appropriate for reliable measurement of surface corrugations can be chosen. The latter are often employed for monitoring film formation in polymer latex systems.

Many polymer surfaces show morphological features with various degrees of order and regularity. The surface topography of liquid crystalline polymers reflects their regular architecture, which correlates with their optical behavior. An optical micrograph and AFM images of a cholesteric liquid crystalline copolymer, which both reveal a focal-conical texture, are presented in Figure 21(a) and (b).\textsuperscript{37} Thermal annealing of this copolymer at 153°C induces its transition from the focal-conical to the fingerprint texture, Figure 21(c). Selective optical reflectivity of the cholesteric copolymer is directly related to its texture and its spectrum correlates with the width of rings of the fingerprint texture seen in the AFM images.

Another example of a polymer sample with well-defined morphology is an industrial film of microporous isotactic polypropylene (iPP) (Celgard\textsuperscript{™} 2400). The morphology of this film, which was examined with SEM and AFM (Figure 22a–c), is characterized by alternating fibrillar and lamellar regions.\textsuperscript{38} The lamellar regions are slightly elevated compared to the fibrils. The latter are not closely packed and, therefore, precise profiling of these fibrils with an AFM tip might be difficult owing to the tip convolution. These structural features (fibrils and holes between neighboring fibrils) are more correctly reproduced in the SEM micrograph (Figure 22a) than in the AFM height image (Figure 22b). However, visualization of the polymer nanostructure is superior with AFM, which is evident from the phase image in Figure 22(b). Therefore AFM is useful for detection of minor structural changes in polymers caused by various technological treatments. Comparison of the images of the Celgard\textsuperscript{™} 2400 membrane prior to and

![Figure 20](image-url)
after argon plasma treatment (Figure 23a and b) shows drastic changes in its nanostructure, whereas overall morphological features remain the same. These changes are caused by condensation of small water droplets from air. It happens because the plasma treatment makes the iPP surface hydrophilic.

Visualization of the morphology and nanostructure of ultrathin polymer films is a capability offered only by AFM. The height image of poly(ε-caprolactone) (ε-PCL) grafted to a Si surface (Figure 24) demonstrates this capability. The image shows the crystalline morphology of a 10-nm thick ε-PCL film, which was prepared by spin casting. Numerous fibrils are spread over the surface along with flat lying lamellar sheets. These parts of growing two-dimensional (2D)-spherulites are the main structural features of the crystalline layer. A deficit of material prevented complete coverage of the substrate surface, and the cross-section profile taken along the x-axis, which is shown above the image, can be used for thickness measurements. The same measurements of thin polymer or organic layers, which cover the substrate completely, can be facilitated by scratching away part of the thin layer.
the layer with an AFM tip in high-force imaging (contact mode will be better for this purpose).\(^{[40]}\)

Thin films and layers of block copolymers are routinely examined by AFM. The height and phase images of a thin layer of PS-\(b\)-PMMA, which was transferred on to a mica substrate from a water subphase in the Langmuir–Blodgett trough, are shown in Figure 25(a–c).\(^{[41]}\) Hydrophilic PMMA blocks are spread as a first layer, whereas hydrophobic PS blocks aggregate on top. Imaging in light tapping allows evaluation of the thickness of the PS blocks (25–30 nm) and visualization of fine details (5–8 nm) of these blocks, Figure 25(c).

The phase separation in the vertical dimension, which exists in this block copolymer film, defines a different response of the PS and PMMA blocks to the AFM probe with hard tapping. With the increase of the tip force, PS blocks are deformed more substantially than PMMA blocks. This is seen from the reduced brightness of PS blocks in the height image and dark appearance of these blocks in the phase image (Figure 25b). In other words, PS blocks, which are further from the substrate than PMMA blocks, are compressed by the probe to a larger extent than PMMA blocks, which lie directly on the substrate. When the tip force was reduced again,
the images became the same as in Figure 25(a), which is an indication of the reversible character of the sample deformation.

3.2 Surface Topography in Heterogeneous Polymer Samples

In studies of the topography of thin films which do not cover the substrate completely, and surfaces of other heterogeneous polymer samples, one should be aware of the possible drawbacks of AFM imaging when the topographic differences are a few nanometers in height. These polymer samples, which in addition are soft, are nontrivial for AFM topographic studies. Application of the contact mode for this purpose could induce sample deformation, which will be different for different sample components. Therefore, the height image will not reflect the surface topography correctly. There is also a problem in tapping mode applications. This problem is caused by the shift of the resonant frequency of the cantilever that leads to a drop in the cantilever amplitude measured at the resonant frequency of the free-oscillating cantilever. Therefore, when surface regions exhibit different properties (e.g. adhesive, mechanical, etc.), which cause different frequency shifts, then corresponding surface areas could appear in the height images with a fake topographic contrast, which is in range of the few nanometers. This effect, which is intrinsic to the tapping mode with amplitude feedback, should be considered while studying surface corrugations of a few nanometers in scale.

Figure 23 (a) AFM images of microporous polypropylene film Celgard™ 2400. (b) AFM images of the same area as in (a) after Ar+ plasma treatment. Scan size 3 µm × 3 µm in all images.

Figure 24 Height image of a 10-nm thick film of ε-PCL grafted to a Si surface. Scan size 4 µm × 4 µm. The cross-section profile shown above the image was taken along the (→←) direction.

Height images of an ultrathin film of PS-b-PMMA block copolymer, which was prepared by spin-coating on Si substrate, will be discussed to illustrate these effects. The way to minimize these effects will also be shown. Typically, the height images of this film show small height variations of PS and PMMA blocks, which reveal microphase separation in such polymers.² The image of the PS-b-PMMA film in Figure 26(a) reveals the microphase separation by showing a pattern similar to that usually determined by TEM. Although in TEM micrographs the different contrast in the PS and PMMA blocks is explained by thinning of the PMMA regions caused by electron beam-induced degradation, the reason for the contrast in the AFM images is not well understood. The fact that in Figure 26(a) and (b) a contrast is seen both in the height and phase images indicates that the probe interacts differently with PMMA and PS blocks. This causes variation of the “heights” of the corresponding regions, with some being higher than others in the height image recorded with light tapping, and lower in the
height image recorded with hard tapping. True sample topography for this sample was recorded by imaging with a softer Si probe, Figure 26(c). The height image recorded with light tapping (Figure 26c, top) reveals no differences in the height of PS and PMMA blocks. The fact that the corresponding phase image is almost featureless indicates that the tip interactions with PS and PMMA blocks are negligible. With hard tapping, these interactions become different causing a microphase contrast in the height and phase images (Figure 26c, bottom). This example shows that imaging in different operation regimes using probes of different stiffness is a way towards rational interpretation of AFM images.

3.3 Nanoindentation and Related Techniques

In addition to surface topography studies, AFM can be employed to evaluate mechanical properties of sample surfaces and polymer coatings. It has already been demonstrated that force curves could be employed for this purpose. As an extension of this approach, nanoindentation, scratching or wear experiments with standard Si probes or with special diamond probes can be used.\textsuperscript{43} There are definite advantages to these modes in comparison with similar macroscopic procedures. They are related to new mechanical measurement capabilities on the micrometer and submicrometer scales. A broad range of low forces, which can be used for nanoindentation and scratching, allows examination of thin and ultrathin coatings without the need to account for substrate influences. Another advantage of AFM use for such studies is that deformation and fracture marks are made and are evaluated with the same instrument. Although nanoindentation and scratching studies with AFM are performed in a number of industrial applications, the question of the transferability of these data to macroscopic mechanical testing has been raised and needs further investigation. Two examples, which are chosen to demonstrate nanoindentation on polymer samples, are shown below.

A matrix of indents, which were made with a diamond tip on the microlayer PE sample (see section 2.3), is shown in the height image in Figure 27(a). This image was obtained several minutes after the indents were made. From the cross-section profiles taken along the indents in neighboring layers (Figure 27b) it can be seen that the indents in a ULDPE layer are larger at the base but shallower than the indents in the high-density PE layer. The difference in the indents' base is related to differences in the elastic moduli of these layers. The differences in the indents' depth reflect partial recovery of the indents in the rubbery ULDPE layer. The combination of nanoindentation with a heating accessory looks very promising because it could allow the indents’ healing to be monitored at different temperatures.

Another example of nanoindentation of two different polymide films, which were deposited on the Si substrate by spin coating, is given in Figure 27(c) and (d). The indents were made at different tip forces and the size of the indents increases accordingly. These data can be analyzed in terms of microhardness (tens to hundreds of newtons per square millimeter range) by dividing a load on the projection area of the indent. Also the shape of the indents on these films is different. Hill locks on the

ATOMIC FORCE MICROSCOPY IN ANALYSIS OF POLYMERS

4 HIGH-RESOLUTION IMAGING OF POLYMER STRUCTURES

Earlier AFM applications to polymer materials included studies of polymer morphologies on the micrometer and tens of micrometers scales and detection of molecular order in oriented samples and single crystals. At present, most efforts are concentrated on the imaging of polymer structures at the submicrometer scale. Such high-resolution imaging substantially complements TEM and diffraction techniques, which are used for analysis of nanometer-scale structures of polymers. In addition to imaging periodic lattices of highly drawn polymer films and single polymer crystals, these studies include visualization of individual polymer chains, the nanostructure of crystalline polymers and oriented samples, and microphase-separated morphologies of block copolymers. Although sample preparation for submicrometer AFM imaging might be nontrivial, in many cases it does not require thin sectioning, etching and staining, which is used for TEM of polymers. Direct visualization of nanometer-scale structures provided by AFM facilitates structural interpretation of the results of other characterization techniques. These data, for example, are invaluable for a correct choice of structural models employed for a rational analysis of diffraction data. However, the question of how surface structures, which are seen in AFM images of polymers, reflect their bulk structure should always be considered.

Several examples of high-resolution images are collected in this section, other examples can be found in following sections.

4.1 Visualization of Single Polymer Chains

Visualization of single DNA macromolecules deposited on different substrates was among the first exciting AFM applications. Because DNA molecules of different lengths are generated in many ways, the sizing of DNA is the subject of many analytical approaches in molecular biology. For AFM studies, DNA molecules should be attached to a solid substrate first, and then imaged in air or in liquid with minimal tip–sample forces. The macromolecules appear as elongated strands in the images, Figure 28(a), and their contour length corresponds to the length of DNA as defined by the number of base pairs. Therefore, histograms that represent the contour length of the macromolecules seen in AFM images shows the molecular weight distribution of DNA. Nowadays, AFM

borders of the indents, which are most pronounced in Figure 27(c), indicate plastic deformation of the polymer during indentation. Similar effects are observed in AFM images of scratches, which are made in mar studies of polymer coatings.\(^{(44)}\)
is routinely used for examination of the shape and conformation of DNA strands, for observation of DNA kinks and for studies of DNA–protein complexes. Although the DNA length is correctly reproduced in the AFM images, its height and width cannot be determined precisely owing to tip-induced deformation and convolution of the apex shape of the tip on the macromolecule. The same is true for imaging of single polymer molecules. This problem might be resolved in the future with the introduction of sharper AFM probes and further lowering of the tip–sample force interactions.

Although AFM imaging of individual polymer macromolecules was demonstrated earlier, it has only recently attracted a broad attention of researchers. The visualization of single polymer molecules and their transformation from a close-packed arrangement to an extended chain conformation was achieved in studies of single layers of PS-b-PMMA block copolymer. The block copolymer layer was transferred on a mica substrate from the water subphase in a Langmuir–Blodgett trough. The AFM images of the complete layer of the block copolymer are shown in Figure 25. When an

Figure 27 (a) Height image showing indents in multilayer PE obtained with 200-µN force. Scan size 10 µm × 10 µm. (b) Profiles of the indents. (c) and (d) Height images showing indents made in two different polyimide layers with different tip forces. Scan size 3 µm × 3 µm in both images.
incomplete layer of PS-\textit{b}-PMMA was transferred on mica, only “islands” consisting of a bottom layer of condensed PMMA blocks and PS blocks on top were seen in AFM images. With an increase in humidity, chains of PMMA blocks underwent a conformational rearrangement from the close packed to the expanded, Figure 28(b). It is most likely that a thin water layer formed on the mica substrate facilitated this chain unfolding.

Visualization of polymer macromolecules is essential for characterization of novel polymers, which are synthesized for possible application in nanotechnology. Molecular conformations of monodendron-jacketed polymers have been examined by AFM. The image of single macromolecules of jacketed PS, which have been deposited on a graphite substrate from a very dilute solution, is seen in Figure 29(a). The macromolecules exhibit a cylindrical shape and worm-like conformation. Alkyl chains, which are present in side groups, lead to

**Figure 29** (a) Height image of single chains of monodendron-jacketed PS (structure illustrated) deposited on graphite. Scan size 0.51 \( \mu \)m \( \times \) 0.51 \( \mu \)m. (b) Histogram of the length distribution of monodendron-jacketed PS.
some orientation order of the macromolecules adsorbed on graphite. A histogram of the length distribution of these macromolecules has been obtained from AFM images and is shown in Figure 29(b). These data complement the molecular weight distribution obtained by size exclusion chromatography and light scattering. In particular, all these methods have been applied to studies of polymacromonomers with a methacrylate main chain and, for the first time, the length per monomer of the cylindrical brush molecules was determined in solution and in the dry state.\(^{49}\)

Direct visualization of polymer chain branches (some are seen in Figure 29a) is another attractive feature offered by AFM. This analytical capability is important because of a strong dependence of polymer properties on type and amount of branching. Further expansion of AFM visualization of single polymer molecules depends to a large extent on the sample preparation, which includes a proper choice of substrate and on the deposition method for spreading single macromolecules on the substrate.

### 4.2 Morphology and Nanostructure of Crystalline Polymers

AFM analysis of the morphology and nanostructure of a number of crystalline polymers provides a means for better understanding their structural organization. In particular, AFM data can be employed for the rational interpretation of the results of electron microscopy and diffraction techniques. An optical micrograph and AFM images of banded spherulites of HDPE/LLDPE (linear low-density polyethylene) blends are shown in Figure 30(a–d). These structures were studied in 1959, when only optical microscopy was available.\(^{50}\) Banded spherulites found in several polymers are seen in optical microphotographs as sets of concentric extension rings caused by a birefringence phenomenon, Figure 30(a). This implies an alternative orientation of PE chains in the spherulites. In other words, the molecular axis (c is along the chain in PE) repeatedly changes its orientation at the location of the rings. It has been shown that the chain axis spirals around the radial direction. Surface corrugations associated with the banded spherulitic patterns are seen in an AFM image of the same sample (Figure 30b). It is most likely that the sample topography with elevated ring structures is the result of extraction of amorphous material as a result of permanganate etching applied to this sample. At greater magnification, the height and phase images reveal that the lower regions consist of linear structures with a width of ca. 20 nm. They also exhibit a well-defined pitch along the main direction, Figure 30(c) and (d). These linear structures could be assigned to the edges of the lamellae. Polymer chains in these regions are oriented in a tangential direction with respect to the spherulite radius. Elevated structures actually represent the main surfaces of the lamellae, which left the bulk material and adopted a flat-on orientation on the surface being examined. In these regions PE chains are oriented perpendicular to the surface. Therefore AFM images confirm that the change in PE chain orientation is responsible for birefringence of the banded spherulite. The phase image in Figure 30(d) shows that flat lamellar surfaces exhibit a granular structure, and this structure is responsible for the appearance of the pitch along the lamellar edges.

A granular nanostructure was found in AFM images of other PEs, ranging from single crystals grown from dilute solutions to samples of ultralow-density material.\(^{51}\) Most of these images were obtained on the surface of melt-crystallized samples, which were not subject to any treatment. Spherulitic morphology and nanostructure of a low-density polyethylene (LDPE) sample, which was melt-crystallized, are presented in Figure 31(a–c). A large-scale height image shows that the spherulite of LDPE is not as well developed as the one shown in Figure 30(a). The height image, which was obtained on a part of this spherulite with light tapping, reveals the granular structure of the LDPE surface, Figure 31(b). With the force increased, the same region in the height image in Figure 31(c) is seen as being composed of a number of fibrils. These changes are reversible, and the grain structure is restored when the force is lowered again. Actually, the height image obtained with hard tapping resembles typical TEM micrographs of PE samples (Figure 31d), where bright linear strips represent lamellae. Because of chemical staining applied to PE samples in TEM, which is applied to provide a contrast between regions of different density, some details of polymer nanostructure can be omitted. Therefore, AFM images, which show not only a denser core with chain folding but also PE nanostructure with a compliant grain shape that is due to a less ordered exterior, describe the crystalline architecture of polymers more accurately. In other words, the fibrils present a more rigid core of linear sequences of several grains that merge with each other. This core is made from chain-folded polymer molecules. Under appropriate crystallization conditions, chain folding of linear polymer chains will be more extensive thus leading to formation of 2D-lamellae. In particular, this happens in single crystals of polymers, whose surfaces, however, still exhibit grain substructure.\(^{51}\) A tentative structural model, which describes the nanostructure of crystalline polymers, is presented in Figure 31(e).

For polymer molecules, whose geometry does not facilitate chain folding, the grain nanostructure can be dominant. One of the relevant examples is ULDPE polymer with a large number of branches. AFM images of
melt-crystallized ULDPE are shown in Figure 32(a) and (b). Again, as in the case of LDPE, the grain nanostructure is seen mostly in the height image recorded with light tapping, Figure 32(a). When the force is increased, the same surface location is represented by a core structure which consists of relatively short lamellae or fibrils arranged into a network, Figure 32(b). This architecture is most likely to be responsible for the rubber-like behavior of this polymer. A similar nanostructure was also observed in PE with a slightly higher density of 0.87 g cm\(^{-3}\). The changes observed in these AFM images have a reversible character.

Further evidence of the grain nanostructure of crystalline polymers is presented in images of melt-crystallized iPP, Figures 33 and 34. A large-scale height image (Figure 33a) shows iPP spherulite of the melt-crystallized sample. Part of this spherulite is presented at higher magnification in the height and phase images shown in Figure 33(b) and (c). Although there are tangential- and radial-aligned structures inside the iPP spherulite, small grains of 10–12 nm in diameter could be considered as elementary blocks of its architecture. These grains are distinctively seen in the phase image and some of them merge with neighbors to form linear tangential
Figure 31 (a–c) AFM height images of melt-crystallized LDPE sample. Scan size 12 µm × 12 µm in (a) and 680 nm × 680 nm in (b) and (c). Images in (b) and (c) were obtained on the same location with light and hard tapping, respectively. (d) TEM micrograph of PE lamellae. (Reproduced from R.L. Morgan, M.J. Hill, P.J. Barham, Polymer, 40, 337 (1999).) (e) Tentative model of nanostructure of crystalline polymers.
and radial sequences. It is worth noting that the structures are best seen in images recorded at relatively small tip-sample interactions. As seen from the phase image, the surroundings of the grain exhibit dark contrast indicating the presence of amorphous polymer in these locations (see section 5.1). With a force increase, the individual grains are not well distinguished because of the increased tip force-induced deformation and larger tip-sample contact area. In such cases, grain sequences are seen as fibrils.

Low-force imaging helps individual grains in iPP spherulites in the crystalline samples prepared not only from melt but also from solution to be visualized. Traces of the grain nanostructure are distinguished in AFM images of epitaxially crystallized iPP samples. The morphology of epitaxially crystallized iPP on anthracene is characterized by linear structures aligned along the main crystallographic axes of the low-molecular weight crystals, Figure 34(a) and (b). At higher magnification, these structures exhibit a pitch along the main direction, Figure 34(c). The presence of granular or block nanostructure was reported in a melt-crystallized sample of syndiotactic polypropylene. The nanoscale surface corrugations, which are related to the grains (blocks) gradually vanished with thermal annealing of this sample. Therefore, the fibrillar structures present in polymer spherulites can be described as linear sequences of tightly packed grain structures, which have a common dense interior formed from chain-folded molecules. Molecular-scale AFM images obtained in contact mode reveal packing motifs of the molecules.

AFM studies of crystalline polymers suggest that individual grains rather than lamellae and fibrils can be considered as the elementary building blocks of crystalline architecture. For polymer molecules, whose chain structure is not flexible enough for extensive chain folding, grains of various sizes are seen inside spherulitic structures. This is the case for copolymers of CPESTs, polyketones, poly(ethylene terephthalate) and other polymers. Although grains in the nanometer size range have been found in a large number of TEM micrographs of various polymers, their unambiguous assignment to true polymer structures was not possible owing to the involvement of chemical etching or staining in the sample preparation. This is not a problem for AFM imaging and the existence of grain nanostructure is no longer in question. This viewpoint is not yet the dominant one, however, it is in accordance with already known theoretical approaches and experimental data. In a polymer textbook, Strobl suggested that the primary step in polymer crystallization is the unmixing of crystallizable and noncrystallizable chain parts, since this necessarily has to precede the formation and growth of crystallites. This process most probably leads to the formation of an individual grain with chain folding in its interior and with a less ordered exterior. Further crystalline growth could lead to more extended fibrillar and lamellar structures.

4.3 Nanostructure of Oriented Samples

The deformation of polymers is a routine procedure that takes place during different technological processes and is used for preparation of high-performance polymeric materials with outstanding mechanical properties. Therefore, understanding the morphology and nanostructure of
oriented materials is of great fundamental and practical importance. Again, AFM could be an invaluable addition to other techniques, which are employed in the study of oriented polymers. AFM measurements of oriented polymers have been conducted for a number of years, starting with the molecular-scale imaging of elongated PE, iPP, polybutene-I and PTFE chains.\textsuperscript{14–17} However, the observation of individual polymer chains is not of primary interest in such applications because observation of molecular-scale defects, which define primary events in the mechanical behavior of polymers, are not accessible with AFM. Therefore, AFM studies of the nanostructure of oriented samples, which is not completely characterized by other methods is most important.

Two examples of morphology commonly found in oriented polymers are shown in Figure 35(a) and (b). They show that though the fibrillar morphology dominates in oriented materials (Figure 35a) lamellar regions oriented perpendicular to the drawing direction can often be seen. This is observed in the images of a microporous iPP membrane (Figure 22) and in the images of melt-blown polymer films, Figure 35(b). AFM images
of the ultradrawn PE fibers (Spectra™ 1000), whose nanostructure is considered to be fibrillar on the basis of X-diffraction studies, revealed tiny nanofibrils of 5–7 nm in diameter. These nanostructures could be described as crystallites with fully extended chain crystallites, which are responsible for the ultrahigh modulus of these materials. However, in addition to nanofibrils, a large number of different lamellar structures were also detected in the topmost layer. To improve the adhesion of such fibers to the polymer matrix in composites their surface was etched with fluorine gas and the related surface changes were distinguished in AFM images.

Oriented tapes of ultrahigh-molecular weight polyethylene (UHMWPE) with different draw ratios have been extensively studied with AFM in the contact and tapping modes. The fibrillar morphology of these tapes has been characterized by bundles of microfibrils with diameters in the 4–7-micron range, by individual microfibrils with diameters between 0.2 and 2 µm and nanofibrils with diameters in the 5–10 nm range. All these fibrils are oriented along the stretching direction and they are...
present in the sample bulk. Low-force imaging of the UHMWPE tapes, which was achieved in imaging under water, showed the presence of a weakly bound overlayer formed from nanofibrils (3–5 nm in diameter), which are oriented perpendicular to the stretching direction.58

AFM images of LLDPE film before and after uniaxial deformation are shown in Figure 36(a) and (b). The original material consists of “islands” of lamellar aggregates embedded into an amorphous polymer (see also section 5.1 and Figure 40). During the uniaxial stretching, plastic deformation occurs with the formation of a neck. In the necked part of the LLDPE sample, previously amorphous regions have been transformed into fibrillar domains and the lamellar aggregates were deformed in the draw direction, Figure 36(b). On further deformation all of the material becomes fibrillar.

The evolution of the crystal morphology during deformation proceeds in different ways but clarification of the polymer nanostructure and its changes during orientation is the key to a rational description of structural changes induced by deformation. In addition

Figure 35 (a) AFM images of uniaxially drawn PE tape (draw ratio 70) and (b) PE film drawn from melt. Scan size 0.5 µm × 0.5 µm in (a) and 1 µm × 1 µm in (b).

Figure 36 AFM images of LLDPE film before (a) and (b) and after (c) and (d) uniaxial stretching. Scan size 20 µm × 20 µm in all images.
to uniaxially drawn polymer materials, biaxially oriented films have been studied with AFM. The morphology and nanostructure of biaxially oriented PVDF film is shown in Figure 37(a) and (b). The morphology is characterized by linear structures, which are aligned in the perpendicular direction. At higher magnification, tiny fibrils (3–5 nm in diameter) and shish-kebab structures have been seen in the phase images. The visualization of lamellar organization in the blown polymer films, which is achieved in AFM images (Figure 38), is of primary importance for the description of polymer orientation and its correlation with the mechanical properties of these films. Diffraction techniques, which are routinely used for these studies, require structural models for the interpretation of data. The most rational models could be built based on the AFM images, which directly show lamellar orientation. Comparative studies of biaxially oriented PE films with X-ray diffraction, electron microscopy and AFM have been performed.\(^5\) Since then, AFM imaging has been further improved and observation of lamella structures in different polymer samples is a routine procedure.\(^6\)

A choice of the parameters for AFM imaging is also important in studies of oriented polymer samples. Even in the contact mode, in AFM studies of oriented polymers

**Figure 36** (Continued)
which were performed before the appearance of the tapping mode, the important role of the tip–sample force interactions was found. Images of the oriented film of UHMWPE (draw ratio of ~8) obtained at different tip forces are shown in Figure 39. With increased force on the nanofibrils, which are oriented along the drawing direction, regions with alternating contrast can be distinguished. Molecular-scale images taken along the fibrils reveals alternation of bright regions with extended chains with those which exhibit inferior order, Figure 39(c). These variations are of ~25 nm and correlate with the long period found in small-angle X-ray scattering (SAXS) patterns of oriented polymer samples. A structural model, which is commonly used for a description of these features, is shown in Figure 39(d). It is also consistent with AFM data. The contrast in AFM images along the nanofibrils could be explained...
by stiffness variations, which are due to more and less regularly arranged PE chains.

The appearance of the long period contrast in high-force AFM images obtained in the contact mode was only achieved by damaging the topmost polymer layer. In tapping mode, the long-period contrast was also observed in hard tapping, Figure 40(a) and (b). The image changes observed on transition from light tapping to hard tapping were reversible. This means that in contrast to variable force imaging in the contact mode, observation of the long period features in the tapping mode occurs without sample damage. Here, it is worth noting that the grain nanostructure, which is seen in AFM images in a number of crystalline polymers, is of the same dimensions as the long period observed in oriented polymer samples. However, the grain nanostructure is observed only in low-force imaging and it is related to the exterior shape of the folded-chain core, whereas the long period variations are related to the alternation in order along the fibrillar core, and they are detected in high-force imaging.

Figure 40 AFM images of oriented PE film obtained on the same location in (a) light tapping and (b) hard tapping. Scan size 1.22 µm × 1.22 µm.
5 COMPOSITIONAL IMAGING OF HETEROGENEOUS POLYMER SYSTEMS

Structural heterogeneity is a common feature of many polymer samples. This is true not only for polymer blends and block copolymers, but also for most crystalline polymers in which amorphous material is a necessary component. Only amorphous polymers such as atactic PS or PMMA could be considered as homogeneous. In characterizing heterogeneous polymer systems, knowledge of distribution of components is one of the most important properties. When applying AFM to such characterization one should realize that optimization of experimental parameters is essential for high-contrast mapping of multicomponent polymer samples. In many cases, this is achieved with hard tapping and the images demonstrate the distribution of individual components on the sample surface. When the probe in a polymer sample passes the viscoelastic top layer, it can penetrate into the sample and subsurface structures can be seen in the images obtained at the elevated tip forces.

The examples, which are given below, show that AFM is a powerful technique for compositional imaging of heterogeneous polymer systems.

5.1 Visualization of Amorphous and Crystalline Components

In analysis of AFM images of crystalline polymers it had been shown that the less ordered exterior surrounds close packed core in grains, fibrils and lamellae. This top layer could be described as an amorphous material bound to the crystalline structure. Traces of free-amorphous material were observed in the phase image of iPP spherulites, Figure 33(c). Additional amorphous components such as wax in industrial PE films, might dominate in surface layers. This is evident from AFM images of LLDPE blown film, which were obtained at different A_{sp}, Figure 41(a–c). In light tapping, only a slight surface corrugation is seen, but with the increase in the tip force the fibrillar aggregate appears more and more distinctively. Similar changes have been seen in the phase images. In this case, the probe penetrates through the topmost amorphous layer, which is in the rubber-like state at room temperature (RT). Therefore, the images at elevated forces show subsurface structures. The estimates of the tip penetration, which were made with the force curves, showed that the image in Figure 41(c) was obtained with the probe ca. 20 nm beneath the top surface.

The way a sample is prepared defines its morphology and nanostructure. Comparison of morphology of a blown LLDPE film and a LLDPE sample that was melt-crystallized with a surface facing Si substrate, is given in Figure 41(d) and (e). The phase image of the LLDPE film shows a number of lamellar aggregates embedded in an amorphous polymer. The surface of the melt-crystallized LLDPE sample is completely covered with lamellae, and some of them are seen lying flat. Both images were obtained with hard tapping but only for the first sample was the transition from light to hard tapping accompanied by drastic changes.

Segmented polyurethanes present structures consisting of hard and soft blocks. In such materials, phase separation may precede crystallization or occur simultaneously. AFM reveals crystalline and amorphous components in such systems. The height and phase images obtained with hard tapping on a micromotmed surface of polyurethane, which was prepared from hard blocks of MDI-butanediol (MDI-diphenylmethane diisocyanate) and soft blocks of poly(ethylene glycol), are shown in Figure 42(a–c). The height image (Figure 42a) shows traces of the microtome knife and several spherulites, which are formed of hard blocks. The spherulites are more pronounced in the phase images (Figure 42b and c), where crystalline structures (bright contrast) are seen.
embedded in amorphous material (dark contrast). The phase image at high magnification (Figure 42c) indicates that individual fibrils, which form the spherulites, exhibit a grain substructure.

Besides amorphous and crystalline forms many polymers also exist in a partially ordered or mesomorphic form. Such organization is common for liquid crystalline polymers and polymers with a flexible

![Figure 42](a) Height and (b) and (c) AFM phase images of microsegregated polyurethane, which were obtained with hard tapping. Height (a) and phase (b) images were obtained simultaneously on 6 µm × 6 µm area. Phase image in (c) was obtained on 0.5 µm × 0.5 µm area.

**Figure 42** (a) Height and (b) and (c) AFM phase images of microsegregated polyurethane, which were obtained with hard tapping. Height (a) and phase (b) images were obtained simultaneously on 6 µm × 6 µm area. Phase image in (c) was obtained on 0.5 µm × 0.5 µm area.
PHASE

Figure 42 (Continued)

Figure 43 AFM images of (a) and (b) PDES and (c) and (d) cyclolinear polysiloxane. Height (a) and phase (b) images were obtained simultaneously on 30 \( \mu \text{m} \times 30 \mu \text{m} \) area. Images in (a) and (b) were obtained with hard tapping. Phase images in (c) and (d) were obtained with light and hard tapping, respectively. Scan size 2.5 \( \mu \text{m} \times 2.5 \mu \text{m} \).

(–Si–O–) backbone. AFM images of several mesomorphic polysiloxanes will be discussed below and also in section 6. The height and phase images of several poly(diethylsiloxane) (PDES) patches, which were deposited on Si substrate by rubbing, are shown in Figure 43(a) and (b). The images were obtained with hard tapping. The height image shows striated droplets of polymer that do not wet the hydrophobic Si surface. The phase contrast indicates three different materials present on the surface. The locations of Si substrate are the brightest, whereas dark spots belong to amorphous PDES. Within the polymer droplets brighter lamellar aggregates are seen, which are oriented perpendicular to the rubbing direction. They are practically indistinguishable in the height images. The presence of extended chain organization in PDES lamellae was suggested from X-ray diffraction and electron microscopy data. Structural reorganization that occurs on heating and cooling of these samples is described in section 6.

Heterogeneity of another mesomorphic polymer, cyclolinear polysiloxane is evident from the phase images recorded with light and hard tapping, Figure 43(c) and (d). Traces of planar structures, which are seen with light tapping, can be assigned to lamellar layers lying-flat on the sample surface. With hard tapping, multiple linear features of 20–30 nm in width are seen through all polymer patches. It is most likely that these features represent edges of lamellae, which exist in the sample bulk. In this case, transition from light to hard tapping led to damage of the ordered top layer.

5.2 Imaging Polymer Blends

For illustration of AFM compositional imaging of polymer blends, three types of samples were chosen. They include microlayer samples, rubber toughened plastics and binary latex blends.

A microlayer material with alternating PE layers of different density, which was described in section 2.2, Figure 7 is the most suitable sample for exploring the AFM capabilities for compositional imaging. The
height and phase images of this sample obtained on the microtomed surface are shown in Figure 44(a) and (b). In the height image the interface borders between the wide layers of ULDPE ($\rho = 0.86 \text{ g cm}^{-3}$) and narrow layers of PE ($\rho = 0.92 \text{ g cm}^{-3}$) are barely distinguishable from other scratches left by an ultramicrotome knife. In the phase image these layers can be easily differentiated. The high-density layers are substantially darker than the ULDPE layers that are seen when small $A_0$ are used for these images. (In the phase image obtained with hard tapping, these layers are darker.) The high sensitivity of the phase contrast to density of PE allows the mixing of the components, which proceeds during high-temperature annealing of this blend to be monitored. The phase image obtained on the annealed sample, Figure 44(c), shows that individual fibrillar and spherulitic structures (both seen as dark strips) appear in the ULDPE layer and, especially at the interlayer interface. ULDPE does not crystallize in this fashion, therefore, this image shows that, during annealing, some polymer from the high-density PE layer diffused into ULDPE layer and crystallized when the sample was cooled.

Other effects were observed in AFM images of a microlayer blend of bisphenol A polycarbonate (PC),
and CPEST (Kodarm). The phase images of this sample as-received after coextrusion did not exhibit any different contrast between the PC and the CPEST layers. This could be explained by the fact that the density of these polymers at RT is almost the same. However, it was possible to assign the layers to different components after thermal annealing at 200 °C. This leads to crystallization of the CPEST whereas the PC remains in an amorphous state. The height and phase images of the annealed microlayer blend are shown in Figure 45(a) and (b). The height image shows alternative layers with height variation. This topography is a consequence of sample microtomy at cryogenic temperatures. Scratches from the microtome knife are seen perpendicular to the polymer layer. Both kinds of feature are also present in unannealed microlayer samples. The main result of sample annealing is spherulitic patterns on elevated layers, which enable their identification as CPEST. The phase contrast between the crystalline and amorphous regions is much stronger than between the PC and CPEST layers (Figure 45b). This is another example showing that phase contrast is related to the density of polymer materials.

Figure 44 (Continued)

Rubber-toughened plastics and filled elastomeric systems are among the multicomponent polymer materials with a broad spectrum of practical applications. Compositional mapping of these materials is an essential part of their characterization, which helps in understanding the structure–property relationships of these materials. Initially, compositional mapping of heterogeneous polymer materials is performed in FM mode and, nowadays, tapping mode with phase imaging is applied. Visualization of the component distribution of a rubber-toughened blend of PC and poly(butylene terephthalate) (Xenoym) is best achieved in images obtained with hard tapping, Figure 46(a) and (b). The contrast in the height image, which is mostly related to surface topography, is less informative than the phase image. The latter shows a distribution of two plastic components and rubber particles. The phase image, which was obtained with light tapping (not shown here), exhibits almost featureless contrast.

For many samples, the assignment of phase contrast to particular sample components is not trivial, it is rational to
Atomic Force Microscopy in Analysis of Polymers

Figure 46 (a) and (b) AFM height and phase images of rubber-toughened plastic, which were obtained simultaneously in hard tapping on a flat surface prepared with an ultramicrotome. Scan size 3 µm × 3 µm.

Figure 47 AFM images of a blend of natural and synthetic rubber filled with carbon black. The sample was prepared with a microtome. The images (a) and (b) were obtained simultaneously in hard tapping on 35 µm × 35 µm area. Phase image in (c) was obtained in light tapping. Scan size 4 µm × 4 µm.

Use a correlation installed from studies of model systems, which might have the same components in different ratios. Also a definite correlation between the phase contrast and stiffness of components can be installed from the studies of polymer materials of the same class. For example, in the phase image obtained with hard tapping, inorganic fillers and plastics components are typically brighter than synthetic and natural rubbers. The latter are brighter than oil and other liquid components. Identification of components can be more complicated if the number of components increases and when the fillers are in the shape of small particles, which might exhibit a local mechanical response governed by their surroundings. AFM images of a blend of natural and synthetic rubbers filled with carbon black particles are shown in Figure 47(a–c). Aggregates of carbon black, which are seen as bright patches in the phase image (Figure 47b), are the consequence of the high affinity of carbon black for synthetic rubber. Besides these aggregates, individual carbon black particles are homogeneously spread through other areas, and they are distinguished in the phase image, Figure 47(c), for the most part because of their shape.

In AFM studies of binary latex blends, a correlation between the phase contrast and glass transition temperatures ($T_g$) of individual components was found. These binary blends are made from acrylic latexes which are different in size and exhibit different $T_g$. These blends were prepared from particles of latex A: 128 nm in size and $T_g = 31^\circ$C, latex B: 124 nm in size and $T_g = 11^\circ$C, and latex C: 217 nm in size and $T_g = 20^\circ$C. The height images of the $A_1B_3, B_1C_3$, and $A_1C_2$ blends (subscripts indicate a component part in the blend), which were obtained with light tapping, show individual particles of the surface layer, Figure 48(a), (c) and (e). The differences in $T_g$ of the blend components are emphasized in the phase images of the same areas, which were recorded with hard tapping, Figure 48(b), (d) and (f). In these images, latex particles with higher $T_g$ values always appear brighter. For
example, in the phase image of the AB blend (Figure 48b), one third of the 100-nm latex particles show up brighter which is consistent with the component ratio in this blend.

5.3 Studies of Microphase Separation in Block Copolymers

Various morphologies with microseparation of components are observed in AFM images of block copolymers. For many block copolymer samples, AFM images show microseparation patterns similar to those obtained with TEM on chemically stained ultrathin sections. With the broadening of such applications, it appears that AFM is invaluable for block copolymers with components for which it is rather difficult to find an appropriate staining agent. Though the preparation of block copolymer films for AFM usually gives a flat surface which can be directly used for imaging, the choice of imaging parameters might be nontrivial. As shown above, differentiation between the components of block copolymers is caused by different tip interactions with their blocks and the same interaction could lead to a faked, non-topography related contrast in the height images obtained in the tapping mode. Although tapping mode is the best alternative for imaging soft samples, such measurements of block copolymers should be performed with special precautions.
To illustrate this point, AFM imaging of the triblock copolymer systems, PS-b-PB-b-PS (PB, polybutadiene), will be considered. AFM images of PS-b-PB-b-PS films prepared by spin casting typically show a microphase separation of the PS and the PB blocks, where PS blocks are seen to be brighter in the height and phase images. These images are similar to TEM micrographs of the same block copolymer, which illustrates bulk film morphology. According to X-ray photoelectron spectroscopy (XPS) data and TEM micrographs, which were taken from the cross-sections cut perpendicular to the film direction, the top surface of PS-b-PB-b-PS films consists of PB blocks. To make AFM data more representative of the actual case imaging should be performed at different $A_{sp}$. Then, AFM images obtained with light tapping will show the true surface topography of the top PB layer, Figure 49(a). With a decrease in $A_{sp}$ and a corresponding increase in tip–sample force interactions, the probe will gradually penetrate through the top PB layer, which is 15–20-nm thick, and will reveal microphase separation in the subsurface material, Figure 49(b). Bright “worms” in this image represent stiff lamellae of PS, which is in a glassy state at RT whereas PB is in a rubber-like state. The image changes are reversible which means fast and complete recovery of the PB top layer after tip penetration. The ability of the tip to penetrate and the layer to recover are due to the rubber-like state of the top layer.

The ability of the AFM probe to penetrate through the top surface layers can be employed for layer-by-layer imaging of more complicated block copolymers. In AFM studies of a fluorinated PS-b-PI (PI, polyisoprene) block copolymer, in which fluorosegments are attached to PI blocks, different AFM patterns were observed during

Figure 48 (Continued)

Figure 49  AFM images of PS-b-PB-b-PS film in (a) light and (b) hard tapping. Scan size 1 µm × 1 µm.
The height image obtained with light tapping reveals the topography of the top layer formed by the terminal PI groups, Figure 50(a). The related phase image is featureless and is not shown here. With an increase in the tip force, a more ordered pattern appears, as seen from the phase image in Figure 50(b). The width of individual bright “worms” is in the 6–8-nm range. With a further increase in force, the phase image changes again and patches with different contrast are seen on the larger scale, Figure 50(c). These image changes are reversible and they indicate a complex layer-by-layer self-organization in this film. For a tentative explanation of these images, several structures were suggested, however, the final conclusions could be drawn only after combined consideration of AFM images and data from other techniques.

6 EXAMINATION OF POLYMER THERMAL TRANSITIONS

After the first steps in AFM characterization of polymers are done, it is important to extend the measurements...
from ambient temperature to temperatures where polymer phase transitions occur. Visualization of structural changes at polymer thermal transitions could be an important addition to a number of macroscopic thermal techniques (DSC (differential scanning calorimetry), TMA (thermal mechanical analysis), DMA, etc.), that are usually employed for studying these transitions. Such studies are in their infancy and they are mostly performed at elevated temperatures.\(^{68-71}\) Only a few studies were undertaken at subzero (°C) temperatures. There are two approaches towards studies of polymer phase transitions. In one approach, a polymer sample is heated or cooled, and the images at different temperatures are recorded. The images presented below were obtained in such a procedure. In another approach, the AFM probe, which stays in permanent contact with the sample, is heated and the probe deflection is monitored.\(^{72}\) The probe deflection changes substantially when the probe temperature exceeds glass transition or the melting temperature of the sample. In this way, the polymer material under the probe can be recognized based on its thermal characteristics.

### 6.1 Imaging Polymers at Elevated Temperatures

In earlier AFM applications to polymers, when measurements at different temperatures were not possible, the effect of thermal annealing on polymer structures was examined at RT. After the initial imaging at RT, the sample was heated to the target temperature for some time and then cooled back to RT. In such procedures, morphology changes of a spin-casted PS-\(b\)-PB-\(b\)-PS film were examined. The initial morphology of the film is different from the one shown in Figure 49(b). This morphology and its changes during annealing are seen in the phase images recorded with hard tapping, Figure 51(a–d). As-prepared film is characterized by spherical particles and with lamellar morphology develops with annealing time, Figure 51(b–d). Long-term annealing of bulk PS-\(b\)-PB-\(b\)-PS samples leads to an appearance of “single crystals” formed from extended lamellae arranged into a hexagonal lattice.

With the development of heating accessories, these films were examined at various temperatures, Figure 52(a–d). It appears that in the AFM phase images, recorded under hard tapping, the microphase-separated patterns gradually disappear as the sample temperature approaches \(T_g\) (~100 °C) of the PS blocks. As mentioned before, the difference in mechanical properties of PS and PB blocks is responsible for the AFM contrast observed in this sample at RT. When both components of this block copolymer are in a rubber-like state, the microphase-separation pattern is not detectable with AFM. However, the presence of the microphase separation in PS-\(b\)-PB-\(b\)-PS film at these temperatures is known from the structural data obtained by other techniques.

In the imaging of fluorinated PI-\(b\)-PS block copolymers at temperatures below and above the smectic phase transition (ca. 50 °C)\(^{66}\), the manner in which the AFM probe could detect this transition was determined, Figure 53. At temperatures below this transition, the AFM images obtained with light and hard tapping had practically the same hexagonal pattern, Figure 53(a), which indicates a “rigidity” of the topmost layer. The hexagonal pattern gradually disappeared with the temperature increase, Figure 53(b). At temperatures

![Figure 51](image_url)  
*Figure 51* AFM phase images obtained on PS-\(b\)-PB-PS film directly after spin casing on Si substrate (a), and after annealing at 100 °C after different times (b–d). All images were obtained at RT with hard tapping. Scan size 2 µm × 2 µm.
above 50 °C, the images obtained with light tapping were featureless but with an increase in the tip force a well-defined hexagonal pattern appears again, Figure 53(c) and (d). This implies that at the smectic phase transition the mobility of the top layer increases and the AFM tip can penetrate through and reach the more ordered and, therefore, more rigid structure of the underlying layer.

The first AFM studies of polymers at elevated temperatures were aimed at monitoring melting and crystallization. While imaging a polymer sample around its melting point experimental difficulties should be expected related to the increased stickiness and softness of the premelted polymer even in tapping mode. This is indeed the case, and for stable imaging at elevated temperatures larger free amplitudes and lower set-point amplitudes should be used. Unfortunately, these restrictions reduce the flexibility of measurements with light and hard tapping that exists in imaging at RT.

High-temperature imaging of bulk polymer samples causes more problems than the imaging of thin and ultrathin polymer films on a solid substrate. The presence of the substrate limits of tip penetration into soft materials helps in AFM imaging. An example of such studies is given in Figure 54(a–f), where a sequence of images shows the growth of e-PCL lamellae at a temperature (T = 36 °C) below its melting point. A dendritic structure was growing inside the amorphous polymer, and the change in its dimensions can be used for evaluation of the crystallization rate. In the initial e-PCL film, the polymer was highly crystalline, Figure 24. The sample crystallized at 36 °C exhibits a semicrystalline morphology. This morphology was stable when the sample was cooled to RT. Full crystallization was achieved only when the sample temperature was below RT, Figure 54(e) and (f). The amorphous material between the dendritic structures crystallized into thin fibrils.

6.2 Visualization of Melting and Crystallization of Polyethylene

AFM studies of melting and crystallization of ultrathin layers of different PE samples have been performed. The crystalline layers of ~20 nm in thickness were formed on a Si substrate after it was dipped into a hot PE solution in xylene and taken out. The morphology of this dip-crystallized PE was characterized by 2D spherulites. The phase image in Figure 55(a) shows a part of such a spherulite formed in the LLDPE film. Almost bare substrate locations are seen in the lower left hand corner of this image. In this spherulite, most of the thin lamellae are edge-on oriented. No structural changes were detected after the sample temperature was raised to 80 °C. A further temperature increase to 125 °C (the melting temperature of this polymer in the bulk state) led to complete disappearance of PE lamellae, Figure 55(b). To detect polymer crystallization in this layer the sample temperature was lowered to 102 °C. During the first scans at this temperature, lamella structures appeared in the lower right hand corner of the imaged area, Figure 55(c). At this temperature, the crystal growth occurs relatively slowly with the formation of semicrystalline morphology, Figure 55(d). Patches of amorphous PE are seen at the edges of the area occupied initially by the spherulite. This morphology was unchanged after cooling the sample to RT.
ATOMIC FORCE MICROSCOPY IN ANALYSIS OF POLYMERS

Figure 52 AFM phase images of PS-\textit{b}-PB-\textit{b}-PS film at different temperatures. All images were obtained in hard tapping. (a) $T = 25^\circ C$, (b) $T = 80^\circ C$, (c) $T = 85^\circ C$, (d) $T = 95^\circ C$. Scan size $2 \mu m \times 2 \mu m$.

A more systematic AFM study of melting and crystallization was conducted on an ultrathin film of LDPE. During step-like heating of this sample (the sample temperature was increased by $5^\circ C$ increments followed by imaging) to $90^\circ C$ or to $100^\circ C$ (below the LDPE melting temperature of $115^\circ C$), the 2D spherulites disappeared and large lamella aggregates appeared, Figure 56(a) and (b). This is a consequence of LDPE recrystallization, which leads to the formation of semicrystalline morphology in the ultrathin film. Additionally, numerous holes appeared in this layer which indicates that a dewetting process has accompanied the recrystallization. Estimates of the recrystallization rate from AFM images showed non-linear character for this process, which is in contrast to PE crystallization in bulk. Such a difference is most likely to be caused by a shortage of polymer material in the ultrathin layer. Further heating of the recrystallized sample to the melting temperature of $115^\circ C$ led to the total disappearance of lamella aggregates, Figure 56(c). After cooling the melted sample to $90^\circ C$, the semicrystalline morphology with lamellar aggregates appeared again. On further cooling to RT, the
amorphous material surrounding these aggregates crystallized with formation of small lamellae, similar to the low-temperature crystallization of \( \varepsilon \)-PCL, Figure 54(e) and (f).

Structural changes, which accompany the melting of the ultrathin LDPE layer, substantially depend on the heating rate. This is demonstrated by the images in Figure 57(a) and (b), which show the morphology changes accompanied by rapidly heating the sample from RT to 90°C. 2D spherulites were converted into sheaf-like patterns, which are embedded in amorphous surroundings. The lamellar structure seen on these sheaf-like patterns at lower temperatures gradually disappeared when the temperature was raised above 115°C. The sheaf-like morphology remained at higher temperatures and the thickness of the sheaves increased owing to polymer dewetting of the substrate (Figure 57b). When this sample was cooled to RT, its morphology remained the same and crystallization of the sheaves led to lamellar and granular structures. A more detailed description of these changes can be found elsewhere.(73)
Figure 54 Phase images of e-PCL layers during crystallization at 40°C (a–d) and after complete crystallization at −30°C (e) and (f). Scan size 4 µm × 4 µm in (a–d), 2 µm × 2 µm in (e) and 1 µm × 1 µm in (f).
6.3 Monitoring of Phase Transitions in Mesomorphic Polysiloxanes

The thermal behavior of PDES is described by DSC traces shown in Figure 58. At RT, this polymer is in the mesomorphic state, and it crystallized around 0°C. Complete isotropization of this polymer is observed at temperatures above 40°C. DSC studies were performed on a bulk sample and it is expected that thermal behavior of PDES patches on Si substrate, which are examined with AFM, may be different. The images in Figure 43(a) and (b) show coexistence of amorphous and lamella structures in PDES patches at RT. When PDES was deposited on the Si substrate, which was treated with argon plasma, a more complete polymer layer was formed. Lamella aggregates, which are embedded in amorphous material and are oriented perpendicular to the rubbing direction, are observed in the phase image of the PDES layer, Figure 59(a). Evident changes in the lamella morphology were observed when the sample was cooled below 0°C, Figure 59(b). These changes happened abruptly while the probe was scanning from the bottom of the area. In the higher magnification image (Figure 59c), it can clearly be seen that a linear
substructure (with the tens of nanometers wide features) has appeared on the lamellae. The changes in lamella substructure are reversed when the sample is heated above RT, Figure 59(d). Therefore, these changes are associated with the crystallization of PDES. Visualization of these changes during crystallization from the mesomorphic state and back allows better understanding of the structural architecture of PDES. The dimensions of lamella observed in AFM images of a number of mesomorphic polysiloxanes are consistent with the extended chain organization in PDES lamella.\textsuperscript{74} However, various nanostructures in the 20–40-nm range, which are seen in AFM images, are not completely understood. For example, the image in Figure 59(e) reveals extended nanostructures on the lamellar aggregates at the temperature of the phase transition ($T = 0$ °C).

The structural changes, which accompany the isotropization of PDES and low-temperature crystallization, are seen in AFM images in Figure 60(a–d). With the increased temperature lamella aggregates of the mesomorphic material gradually melt and finally disappear, Figure 60(a) and (b). The largest thermal effect is related to the crystallization of the mesomorphic material around 0 °C (Figure 58). However, this process does not involve

amorphous material, which surrounds the lamella. Deep cooling of the PDES sample to −40°C induced crystallization of the amorphous polymer. The appearance of spherulite-like structures in the bottom right corner of Figure 60(c) and their growth (Figure 60d) can be assigned to the low-temperature crystallization of PDES. Also, new lamellae were grown from the advanced edges of large lamellae.

AFM studies of poly(dipropylsiloxane) (PDPS) at different temperatures reveal structural changes accompanying the reversible crystal–mesophase transition. PDPS differs from PDES in having slightly longer side chains and this change in chemical structure leads to the shift of the thermal phase transition to higher temperatures. At RT this polymer exists in the crystalline state, and the phase image in Figure 61(a) shows crystalline blocks with distinctive edges both of submicrometer size. Upon heating these features disappeared gradually, and in the mesomorphic state all features were disordered.

of the surface was manifested as large lamellar bundles, which are elongated along the rubbing $Y$-direction, Figure 61(b) and (c). On cooling the sample back to $T = 40^\circ$C, PDPS crystallization is seen as an abrupt transformation of the lamellar bundles to the crystalline blocks.

Visualization of polymer morphology and nanostructure changes at thermal phase transitions, which was demonstrated with the images $\varepsilon$-PCL, PE and mesomorphic polysiloxanes, opens up new capabilities for AFM in the characterization of polymers. The most exciting findings are anticipated in the examination of polymer structural changes on the submicrometer scale. Observations of morphology and nanostructure changes during recrystallization of LDPE substantially broadens our knowledge of these processes.

7 EXPECTATIONS

Applications of AFM to polymer materials have been developing progressively. Many aspects of AFM imaging
of polymer samples are already understood, and the results obtained undoubtedly show the value of this technique. In its basic function, AFM provides high-resolution profiling of a surface allowing visualization of the polymer nanostructure and is an invaluable addition to other characterization techniques. However, its capabilities extend far beyond high-resolution imaging. In addition, AFM provides a means of probing of local sample properties and compositional mapping of heterogeneous polymer systems. For some samples, imaging of subsurface structures can be achieved. To realize these capabilities practically, a more thorough experimental approach should be developed, which includes all aspects of AFM analysis: sample preparation, optimization of imaging parameters and image interpretation. There is a lot of room for improvement in these features and they will be realized because of the strong interest in AFM applications of polymers both in academia and in industry. This interest will grow further because AFM complements a large number of other characterization methods. Also for microscopic studies of some polymer systems, e.g. thin
and ultrathin films, AFM is in practice the only technique applicable.

Other expectations are related to instrumental developments that broaden AFM studies of polymers. Only the first steps have been taken in AFM studies of polymers at different temperatures. The same is true of monitoring mechanically induced changes in polymer samples. An advanced picture of nanostructure organization in polymer materials, which is emerging from the combination of AFM results with data from other microscopic and diffraction techniques, will motivate researchers to explore thoroughly nanostructural changes during thermal transitions and mechanical loads.
